AXES (Aircraft). Three fixed lines of reference, usually centroidal and mutually perpendicular. The horizontal axis in the plane of symmetry, usually parallel to the thrust axis, is called the longitudinal axis; the axis perpendicular to this in the plane of symmetry is called the normal axis; and the third axis perpendicular to the other two is called the lateral axis. Rotation may take place about any or all axes; translation may take place along any of the three axes. The important translational axis is the longitudinal. See also **Bank (Aircraft)**; **Pitching Moment**; and **Yaw (Aircraft)**.

AXIAL MAGNIFICATION. The ratio of the interval between two adjacent image points on the axis of an optical instrument to the interval between the conjugate object points.

AXIAL ORGAN. An organ of peculiar structure and unknown function found near the axis of the body in all echinoderms except the sea cucumbers.

AXIL. The angle between the upper side of a leaf and the stem to which the leaf is attached. See **Stem (Plant)**.

AXINITE. This mineral is an aluminum-boron-calcium silicate with iron and manganese, $(Ca, Mn, Fe)_3Al_2BSi_4O_{15}(OH)$. It crystallizes in the triclinic system, yielding broad sharp-edged forms, which has led to its name, derived from the Greek word meaning axe. It breaks with a conchoidal fracture; hardness, 6.5–7; specific gravity, 3.22–3.31; luster, vitreous; colors, brown, blue, yellow and gray; transparent to translucent.

Axinite occurs in granites or more basic rocks along contacts and in cavities in Saxony, Switzerland, France, England, Tasmania, and Japan; in the United States, in New Jersey, Pennsylvania, and California.

AXIOM. A statement of an abstract notion that is assumed without proof. Axioms constitute the unproved first principles used in founding a mathematical discipline. Physical science disciplines sometimes are developed using the axiomatic approach which embraces the presentation of a minimum number of statements (axioms) and derives the other relationships common in the discipline, using only these axioms and mathematical and logical processes.

AXIS. A line so situated that various parts of an object are symmetrically located in relation to it. Also the line passing through the origin of a coordinate system which corresponds to all points of a given variable when other variables are zero. Thus, in two dimensions, the X-axis is the locus of all points whose Y-coordinate is zero. See also **Ellipse**; **Hyperbola**; **Mineralogy**; and **Parabola**.

AXIS (Instantaneous). In rigid body motion, a line perpendicular to the plane of the motion which passes through that point or those points of a body which are instantaneously at rest. For a cylinder rolling down an inclined plane without slipping, the instantaneous axis is the line of contact between cylinder and plane.

AXIS OF ROTATION (Fixed). The locus of points of a system along a straight line that remain stationary when the system undergoes motion of rotation.

AXIS (Optic). A direction through a doubly-refracting crystal along which no double refraction occurs. A uniaxial crystal has one such direction, a biaxial has two such directions. See **Crystal**.

AXIS (Optical). The line through the foci and the vertices of the optical surfaces. Commonly, the surfaces of lenses and mirrors are figures of revolution about the optical axis. Normally, the parts of an optical system are all coaxial.

AXOLOTL *(Amphibia, Urodela).* A salamander, *Ambystoma tigrinum*, found near Mexico City which, although related to some of the terrestrial salamanders, retains its larval form throughout life, becoming sexually mature in this stage. Under experimental conditions the animal has been caused to undergo the usual metamorphosis. See also **Salamander**.

AXON. The impulse-transmitting part of a nerve cell or neuron. The other parts are the cell body, containing the nucleus, and the dendrites, branches that pick up impulses. The axon is also known as the nerve fiber. The axon of a peripheral nerve of a vertebrate animal is typically covered by an inner myelin sheath and by a thin outer cellular layer called the *neurilemma*. In certain invertebrates, such as the squid, giant axons are found which range in size from 150–700 micrometers in diameter. This unusually large size has made possible many fundamental measurements on the biophysical properties of the excitable cell membrane of the axon. See also **Central and Peripheral Nervous Systems and The Brain**.

In contrast to the continuous excitory level of the neuron as a whole, the outflow of energy through an axon exhibits an *all* or *none* response. Thus, it is either quiescent or carries one or more discrete intermittent nerve impulses — only their frequencies differ.

The axon terminals of a neuron may be few in number and concentrate their effect on one or only a small localized group of post-synaptic cells. In other situations, collateral branches arise from an axon at points throughout its course and each of these may itself arborize and diverge to many destinations. The "many-to-one" convergence of information channels with the integration of their effects and, in other situations, the "one-to-many" divergence of channels are essential features of all advanced forms of nervous systems.

AYKROYD, WALLACE RUDDELL (1899–1979). Aykroyd was a British physician who studied nutrition problems in Newfoundland and India, and was a pioneer organizer of international collaboration in this field. The son of a Yorkshire businessman, Aykroyd was born in Dublin and obtained his medical degrees there. His first post, in 1924, was in Newfoundland, where he studied the problem of beriberi in isolated communities. Then he received a fellowship in 1928 to work with Harriette Chick at London's Lister Institute on the assay of foods for their vitamin potency. See also **Chick, Harriette (1875–1977)**.

In 1931 Aykroyd joined the League of Nations staff in Geneva to set up international studies of the world's nutrition problems, and co-authored an influential report, Nutrition and Public Health. In 1935 he became Director of the main nutrition research laboratory in India, and organized systemic studies of the nutritional value of Indian foods and, in particular, the effects of processing rice in different ways. He was also a member of the commission enquiring into the causes of the Bengal famine that occurred during World War II. See also **Nutritional Science (The History)**.

In 1943 Aykroyd had represented India at the international Hot Spring Conference which led to the setting up of the Food and Agriculture Organization (FAO) at the end of World War II. He himself was selected to head the Nutrition Division. This led to a great increase in international collaboration and study of Third World problems. After his retirement in 1960 he continued to lecture at London University and published *The Conquest of Famine*.

AZEOTROPIC SYSTEM. A system of two or more components that has a constant boiling point at a particular composition. If the constant boiling point is a minimum, the system is said to exhibit *negative azeotropy*, if it is a maximum, *positive azeotropy*.

Consider a mixture of water and alcohol in the presence of the vapor. This system of two phases and two components is divariant (see Phase Rule). Now choose some fixed pressure and study the composition of the system at equilibrium as a function of temperature. The experimental results are shown schematically in Fig. 1.

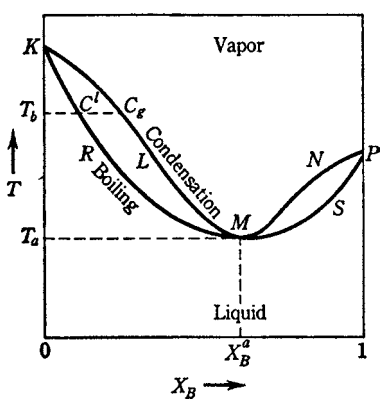

Fig. 1. Azeotropic system.

The vapor curve KLMNP gives the composition of the vapor as a function of the temperature T, and the liquid curve KRMSP gives the composition of the liquid as a function of the temperature. These two curves have a common point M. The state represented by M is that in which the two states, vapor and liquid, have the same composition x_B^a on the mole fraction scale. Because of the special properties associated with systems in this state, the Point M is called an azeotropic point and the system is said to form an azeotrope. In an azeotropic system, one phase may be transformed to the other at constant temperature, pressure and composition without affecting the equilibrium state. This property justifies the name azeotropy, which means a system that boils unchanged.

AZIDES. The salts of hydrazoic acid are termed *azides*. Metallic azides can be prepared from barium azide and the metal sulfate, or from potassium azide and the metal perchlorate.

Soluble azides react with iron (III) salt solutions to produce a red color, similar to that of iron(III) thiocyanate. Sodium azide is not explosive, even on percussion, and nitrogen may be evolved upon heating. With iodine dissolved in cold ether, silver azide forms iodine azide (IN_3), a yellow explosive solid.

Sodium azide is a slow oxidizing agent. It has a selective action in inhibiting the growth of gram-negative organisms. It has been used as a component in selective media such as azide glucose broth or azide blood agar base for the isolation of mastitis and fecal *streptococci*.

A number of alkyl and aryl azides are known, such as CH_3N_3, $C_2H_5N_3$ and $C_6H_5N_3$. The nonmetallic inorganic azides include ClN_3, an explosive gas, BrN_3, an orange liquid, mp $-45\,^{\circ}C$, and IN_3, a yellow solid, decomposing above $-10\,^{\circ}C$. The gas FN_3 is more stable than ClN_3, decomposing only slowly at room temperature.

Lead and silver azides are widely used as initiating, or primary explosives because they can be readily detonated by heat, impact, or friction. As such, these materials, particularly lead azide, are used in blasting caps, percussion caps, and delay initiating devices. The function of the azides is similar to that of mercury fulminate or silver fulminate.

AZIMUTH (Astronomy). That coordinate of the horizontal coordinate system of a celestial object measured in the plane of the horizon to the point where the vertical circle of the object cuts the horizon, from the south to the right (west) through 360°. Astronomical azimuth may be computed by solving the astronomical triangle, provided three other parts are known. In most cases, the latitude of the observer, the hour angle, and declination of the object are the known parts. In case the longitude of the observer is not accurately known, the altitude of the object may be obtained and combined with latitude and declination for computing azimuth. Several of the terms used here are described elsewhere in this encyclopedia.

AZIMUTH MARKER. 1. A scale encircling the plan position indicator (PPI) scope of a radar on which the azimuth of a target from the radar may be measured.

2. Reference limits inserted electronically at 10° or 15° intervals, which extend radially from the relative position of the radar on an off center PPI scope. These are employed for target azimuth determination when the radar position is not at the center of the PPI scope and hence the fixed azimuth scale on the edge of the scope cannot be employed.

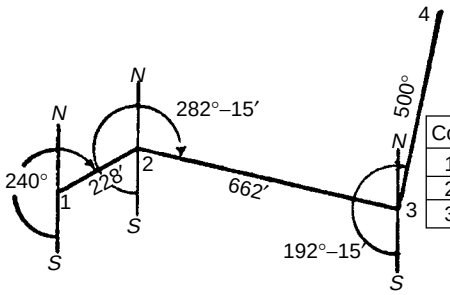
On such markers north is usually 0°, east 90°, etc. Occasionally, on ship or airborne radars, 0° is used to indicate the direction in which the craft is heading, in which cases the relative bearing, not azimuth, of the target is indicated.

AZIMUTH (Navigation). The horizontal direction of a celestial point from a terrestrial point, expressed as the angular distance from a reference direction, usually measured from 0° at the reference direction clockwise through 360°. An azimuth is often designated as true, magnetic, compass, grid, or relative as the reference direction is true, magnetic, compass, grid north, or heading, respectively. Unless otherwise specified, the term is generally understood to apply to true azimuth, which may be further defined as the arc of the horizon, or the angle at the zenith, between the north part of the celestial meridian or principal vertical circle and a vertical circle, measured from 0° at the north part of the principal vertical circle clockwise through 360°. See also **Navigation**.

AZIMUTH (Surveying). The terrestrial azimuth of a mark is usually determined with an altazimuth instrument or surveyor's transit. The difference in azimuth between the vertical circle through some celestial object and the mark is measured and combined with the known azimuth of the object to obtain the azimuth of the mark. The object most commonly used for this purpose is Polaris (the North Star), since this star is within 1° of the pole of rotation, and its azimuth changes very slowly with time. Tables are published in the *Nautical Almanac*, and a variety of other places,

which give the azimuth of Polaris in terms of local date and time. When using the North Star for ordinary surveying purposes, the local time is needed only to within about 5 minutes; but for precise geodetic work, the time must be known to within a few seconds.

Surveyors frequently run a traverse using azimuths and distances. The plotting of a traverse by this method is shown in Fig. 1.



Course	Azimuth	Distance
1–2	240°	228
2–3	282°–15′	662
3–4	192°–15′	500

Fig. 1. Plotting of a traverse.

AZINES. The products of the reaction between an aldehyde or a ketone with hydrazine are termed *azines*. A number of dyestuffs and complex members of the pyridine family of compounds also are termed *azines*. See also **Pyridine and Derivatives**.

AZO AND DIAZO COMPOUNDS. Characteristically, these are compounds containing the group $-N{:}N-$ (azo) or $>N{:}N$ (diazo). They are closely related to the substituted hydrazines. The N_2 group may be covalently attached to other groups at both ends, as in the azo compounds, or at only one end, as in the diazo compounds or diazonium salts. Although organic chemistry furnishes the most numerous examples, many inorganic azo compounds also exist.

Compounds related to aniline, either directly or by oxidation, and to nitrobenzene by reduction, are numerous and important. When nitrobenzene is reduced in the presence of hydrochloric acid by tin or iron, the product is aniline (colorless liquid); in the presence of water by zinc, the product is phenylhydroxylamine (white solid); in the presence of methyl alcohol by sodium alcoholate or by magnesium plus ammonium chloride solution, the product is azoxybenzene (pale yellow solid); by sodium stannite, or by water plus sodium amalgam, the product is azobenzene (red solid); in the presence of sodium hydroxide solution by zinc, the product is hydrazobenzene (pale yellow solid). The behavior of other nitrocompounds is similar to that of nitrobenzene.

Diazonium salts are usually colorless crystalline solids, soluble in water, moderately soluble in alcohol, and when dry are violently explosive by percussion or upon heating.

The simplest azo-dyes are yellow, but by increasing the number of auxochrome groups or by increasing the percentage of carbon, the color darkens to red, violet, blue, and in some cases brown. Naphthalene residues darken to red, violet, blue and finally black. These aminoazo-dyes, together with the hydroxyazo-dyes (containing auxochrome hydroxyl-group $-OH$), are generally only slightly soluble in water. In order that the dye may be soluble it is desirable that it contain one or more sulfonic acid groups $-SO_2OH$. This group may be introduced either by treating the dye with concentrated sulfuric acid, or by using sulfonic acid derivatives in preparing the dye, e.g., methyl orange, sodium dimethyl-*para*-aminoazobenzene-*para*-sulfonate

$$(4)(CH_3)_2NC_6H_4N{:}NC_6H_4SO_2ONa(4)$$

from dimethylaniline and diazotized sulfanilic acid (*para*-amino-benzene sulfonic acid), $(1)H_2N{\cdot}C_6H_4{\cdot}SO_2OH(4)$, and then the sodium salt is made from the product. Other azo-dyes are

$$\text{chrysoidine} \left(C_6H_5N{:}NC_6H_3 \begin{matrix} NH_2(2) \\ NH_2(4) \end{matrix} \right)$$

$$\text{Bismarck brown} \left((3)H_2N{\cdot}C_6H_4N{:}NC_6H_3 \begin{matrix} NH_2(2){\cdot}HCl \\ NH_2(4) \end{matrix} \right)$$

AZORES CURRENT. See **Ocean Currents**.

AZORES HIGH. See **Meteorology**.

AZURITE. This mineral is a basic carbonate of copper, crystallizing in the monoclinic system, with the formula $Cu_3(CO_3)_2(OH)_2$, so called from its beautiful azure-blue color. It is a brittle mineral with; a conchoidal fracture; hardness, 3.5–4; sp gr, 3.773; luster, vitreous, color and streak, blue; transparent to translucent. Azurite, like malachite, is a secondary mineral, but far less common than malachite. It is formed by the action of carbonated waters on compounds of copper or solutions of copper compounds.

AZUSA. A short-baseline, continuous wave, phase comparison, single-station, tracking system operating at C-band and giving two direction cosines and slant range which can be used to determine space position and velocity.

B

BABESIOSIS *(Babesiasis, Piroplasmosis)*. Babesiosis is transmitted by the same deer tick that transmits Lyme disease. Babesiosis is primarily a disease of cattle, caused by a protozoan related to the malaria parasite. The protozoan, *Babesia microti*, after ingestion by its vector, the ixodid hard-bodied tick, grows inside the gut of the insect and spreads throughout its body. Infection of the vertebrate host, which can be either a wild or domesticated animal, occurs when the tick obtains a blood meal from it. Humans do not appear to be a reservoir for the infection and are not commonly affected by the disease. However, they can acquire babesiosis by blood transfusion. The consequences of infection by *B. microti* in humans can range from being asymptomatic to manifestation of a severe and prolonged illness. Typically, there is a gradual onset of fever, chills, sweating, generalized myalgia, fatigue, anemia, and renal insufficiency and failure. Infections by *Babesia divergens* are associated with cattle and are characterized in humans by chills, high fever, nausea, vomiting, and severe hemolytic anemia. Individuals infected with *B. divergens* generally lack functioning spleens and the disease has been fatal in a large percentage of cases. Related infections include *Babesia bigemina*, the cause of Texas cattle fever, and *Babesia bovis*, responsible for hemoglobinuric fever in European cattle.

Babesiosis in humans is frequently self-limiting. Quinine [CAS: 130-95-0] (**1**) plus clindamycin (**2**) is considered the treatment of choice and has also been used effectively to treat transfusion babesiosis (Table 1). Quinine, either alone or in combination with pyrimethamine **3**, has failed to eliminate experimental *B. microti* in hamsters. Babesiosis contracted in the United States has been successfully treated with chloroquine. However, when tested in infected hamsters, chloroquine failed to clear the infection, as did the other antimalarials sulfadiazine (**4**) and pyrimethamine (**3**). There was only a limited response to pentamidine (**5**) and diminazene aceturate [**6**, 4,4′-(diazoamino)dibenzamidine aceturate, Berenil, also diminazene dilactate Babesin]. Pentamidine has been used successfully to treat the symptoms of the disease in humans and in cats infected with *Babesia felis*. Diminazene aceturate is effective against experimental *B. microti* in jirds, but not *in vitro* against *Babesia equi*. Imidocarb [CAS: 27885-92-3] dipropionate is a therapeutic and prophylactic treatment for babesiasis in cattle, gerbils, and other domestic animals. The urea, amicarbalide (**7**) diisethionate [CAS: 3671-72-5] (3,3′-diamidinocarbanilide diisethionate, Diampron) is also used for babesiosis in cattle. *Babesia gibsoni* in dogs has been treated effectively with phenamidine isethionate (**8**). Another urea, Babesan, (**9**), 1,3-di-6-quinolinylurea as the bismethosulfate salt ie, quinuronium sulfate, $C_{23}H_{26}N_4O_9S_2$, is used for veterinary purposes.

Geographic Distribution

Worldwide, but little is known about the prevalence of in malaria-endemic countries, where misdiagnosis as *Plasmodium* probably occurs. In Europe, most cases are due to *B. divergens* and occur in splenectomized patients. In the United States, *B. microti* is the agent most frequently identified (Northeast and Midwest), and can occur in non-splenectomized individuals. Two variants, arguably different species, have been reported in the U.S. states of Washington and California (WA1-type parasites) and Missouri (MO1).

Most infections are probably asymptomatic, as indicated by serologic surveys. Manifestations of disease include fever, chills, drenching sweats, myalgias, fatigue, hepatosplenomegaly, and hemolytic anemia. Symptoms typically occur after an incubation period of 1 to 4 weeks, and can last several weeks. The disease is more severe in patients who are immunosuppressed, splenectomized, and/or elderly. Infections due to *B. divergens* tend to be more severe (frequently fatal) than those due to *B. microti*, where clinical recovery usually occurs. The fact that *Babesia* organisms do not produce pigment in red blood cells is helpful in differentiating the disease from malaria. With the exception of splenectomized patients, babesiosis is generally self-limited and requires no special therapy. Clindamycin plus quinine is recommended as the drug regimen of choice. Exchange transfusion has been used in severely ill patients with high parasitemias, and that combinations including other drugs (such as atovaquone, azithromycin, pentamidine, and trimethoprim-sulfamethoxazole) may also be effective.

See also **Antiparasitic Agents, Antiprotozoals**; and **Lyme Disease**.

BABINET POINT. One of the three commonly detectable points of zero polarization of diffuse sky radiation, neutral points, lying along the vertical circle through the sun; the other two are the Arago point and Brewster point. The Babinet point typically lies only 15° to 20° above the sun, and hence is difficult to observe because of solar glare. The existence of this neutral point was discovered by Babinet in 1840.

BABINET'S PRINCIPLE. An approximation according to which, the amplitude of near-forward scattering by an opaque, planar object is the same as that of an aperture of the same shape and size. Babinet's principle is sometimes combined with Fraunhofer diffraction theory in the development of an approximate theory of the corona.

BABINGTONITE. This mineral is a relatively rare calcium-iron-manganese silicate, occurring in small black triclinic crystals, found in Italy, Norway and in the United States at Somerville and Athol, Massachusetts, and in Passaic County, New Jersey. It was named for Dr. William Babington.

BABOON. See **Monkeys and Baboons**.

BACKDOOR COLD FRONT. See **Meteorology**.

BACK FOCAL LENGTH. The distance from the back surface of a lens to the second focal point. Its reciprocal is sometimes called the vertex power or the effective power of a lens. See **Mirrors and Lenses**.

BACK-GOUDSMIT EFFECT. An effect closely related to the Zeeman effect. It occurs in the spectrum of elements having a nuclear magnetic and mechanical moment. See also **Hyperfine Structure**; and **Paschen-Back Effect**.

BACKING. See **Winds and Air Movement**.

BACKLASH. Also termed mechanical hysteresis, backlash may be defined as that lost motion or free play that is inherent in mechanical elements, such as gears, linkages, or other mechanical transmission devices

TABLE 1. BABESIOSIS ANTIPROTOZOAL AGENTS[a]

that are not rigidly connected. A physical model of backlash is shown in Fig. 1. The characteristic is shown in Fig. 2.

Backlash causes an effect similar to the hysteresis loop of Fig. 3, in that the output magnitude will assume a different value for a given value of input, depending upon whether the input is increasing or decreasing. In the classical definition of hysteresis, the output is not only dependent upon the value of input and the direction of the traverse, but also is dependent upon the history of prior excursions of the input and the span of the immediate excursion. Perhaps the most distinguishing characteristic of hysteresis is that output changes are continuous with the input so that some reversal of the output magnitude will take place for any small reversal of the input. In this sense, the output is multivalued, in that it can assume many values for a given input magnitude, depending upon the factors just described.

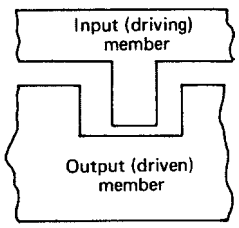

Fig. 1. Physical model of backlash.

For pure backlash, however, the output is double-valued and is determined only by the magnitude of the input and whether it is increasing or decreasing. The total effect of backlash will also show up whenever there is any reversal of input larger (in relative values) than the magnitude of the backlash.

Most devices exhibit characteristics that are an inseparable combination of hysteresis and backlash. For this reason, it is proper to define hysteresis, for static measuring purposes, as a characteristic that includes both hysteresis error (as described above) and backlash.

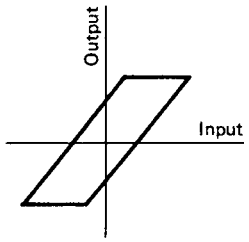

Fig. 2. Characteristic of backlash.

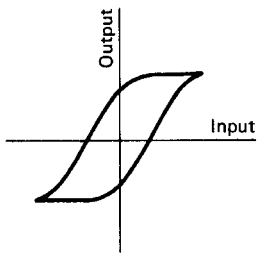

Fig. 3. Hysteresis loop.

The effect of backlash is of particular importance in the dynamic analysis of closed-loop systems. In this sense, the result is a discontinuous nonlinearity with a double-valued output. The describing function of such an element is a complex quantity whose magnitude and phase are both dependent upon the input signal and, if the effect is sufficiently large and not otherwise compensated, it can be a source of system instability.

In nonlinear analysis, backlash is considered to be either friction-controlled, inertia-controlled, or some combination of the two. If the output (or driven element) is considered to have friction, but no inertia, and the peak value of the output will be less than that of the input magnitude. If it is considered to have inertia and friction, and the peak value of the output will exceed the maximum input magnitude. In either case, there will be a phase lag, which is a function of the ratio of the backlash and the peak value of the input sine wave.

BACKSCATTERING. The deflection of particles or of radiation by scattering processes through angles greater than 90° with respect to the original direction of motion.

One particular application of backscattering is the use of beta rays (electrons) to determine properties of substances. This phenomenon has been known for many years, but more recently its variations in value with differences in the atomic and molecular composition of the scattering substance have been found to give results that can be correlated with the atomic numbers of the atoms. In some cases where identical backscattering is obtained from two or more compounds (because of an accidental agreement between the total scattering of their atoms) differences in beta-ray absorption between them are usually available to provide another clue to their composition. Backscattering has also found application in measuring the thickness of coatings on materials such as paper, plastic films, and strip steel.

Backscattering also plays a part in the reception of radio waves, where it is commonly expressed in terms of a coefficient, which is said to measure the "echoing area." For an incident plane wave, the backscattering coefficient B is 4π times the ratio of the reflected power per unit solid angle (ϕ) in the direction of the source divided by the power per unit area (W_i) in the incident wave:

$$B = 4\pi \frac{\Phi_r}{W_i} = 4\pi r^2 \frac{W_r}{W_i}$$

where W_r is the power per unit area at distance r. For large objects, the backscattering coefficient of an object is approximately the product of its interception area and its scattering gain in the direction of the source, where the interception area is the projected geometrical area and the scattering gain is the re-radiated power gain relative to an isotropic radiator.

BACKSCATTER ULTRAVIOLET (BUV) SPECTROMETER. See **Nimbus Satellite Program**.

BACK SHEARED ANVIL. See **Metrology**.

BACK-SWIMMER *(Insecta, Hemiptera)*. An aquatic bug of boat-like form that lives in an inverted position. The hind legs are broadened by fringes and are used like oars for propulsion. Family *Notonectidae*.

BACTERIA. Microscopic, unicellular cells bounded by a membrane-wall complex and containing a variety of inclusions. Depending upon the species and cultural conditions, bacteria occur as individual cells or in clumps or chains of sister cells. Bacteria lie at the lower limits of resolution of the optical microscope. The average length lies within the range of 2 to 5 micrometers, although some are as small as 0.2 micrometer, or as large as 100 micrometers in length.

Bacteria are classified, somewhat arbitrarily, by a descriptive array of features, one of the most common being shape.

Bacilli

In terms of shape, the first of these are rod-shaped and are called *bacilli* (singular, *bacillus*). The bacilli often have small, whip-like structures known as flagella, with which they are able to move about. Some bacilli have oval, egg-shaped, or spherical bodies in their cells, known as spores. Under adverse conditions, such as dehydration, and in the presence of disinfectants, the bacteria may die, but the spores may be able to live on. The spores germinate when the conditions become favorable, and form new bacterial cells. Some are so resistant that they can withstand boiling and freezing temperatures and prolonged desiccation. See Fig. 1.

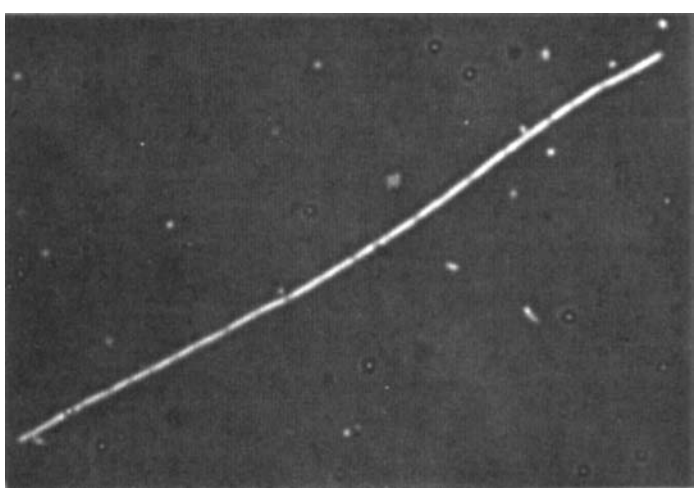

Fig. 1. Bacillus. (*A.M. Winchester*.)

Cocci

A second type of bacteria is the *cocci* (singular, *coccus*) which are spherical or ovoid in shape. The individual bacterial cells of this group may occur singly (*Micrococcus*), in chains (*Streptococcus*), in pairs (*Diplococcus*), in irregular bunches (*Staphylococcus*), and in the form of cubical packets (*Sarcina*). The coccus does not form spores and usually is nonmotile. See Fig. 2.

Curved or Bent Rods

A third group of bacteria are the curved or bent rods. Of these, the genus *Vibrio* is composed of bacteria that are comma-shaped; and the genus

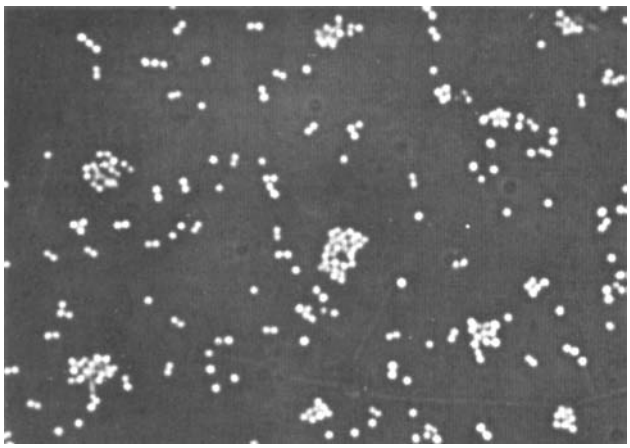

Fig. 2. Coccus. (*A.M. Winchester*.)

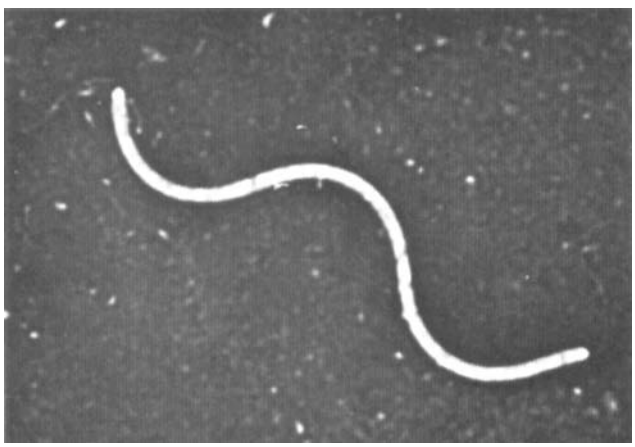

Fig. 3. Spirillum. (*A.M. Winchester*.)

Spirillum consists of those that are twisted and spiral in form. All members of this group are motile, but none form spores. However, some of these bacteria form a gelatinous capsule or covering by which they are probably protected from adverse environmental conditions. Still another group of spiral-shaped bacteria are known as the *spirochetes*, one of which is the cause of syphilis. See Fig. 3.

Other Bases for Classifying Bacteria

Bacteria also may be classified on the basis of their requirements of free atmospheric oxygen. Those requiring atmospheric oxygen are called *aerobic* (air-living); those which cannot live in the presence of atmospheric oxygen are called *anaerobic*; those that do well with oxygen, but can get along without it are termed *facultative anaerobes*.

Bacteria are dependent upon the proper temperature for life and reproduction; and the various species of bacteria may differ widely in their temperature requirements. Most of the disease-producing (*pathogenic*) bacteria thrive best at body temperatures; others may live and multiply in much cooler temperatures; while still others live in hot springs. Freezing, as a rule, does not destroy bacteria, but prevents their reproduction. High temperature, conversely, quickly kills many bacteria. Most disease-producing organisms in milk, for example, may be killed by raising the temperature to 143 °F (61.6 °C) in the pasteurizing process. Most non-spore-forming, disease-producing microorganisms are destroyed by boiling water. In the spore stage, some bacteria must be heated to 240 °F (116 °C) for a considerable period of time, in order that the spores be destroyed. These high temperatures are best obtained by steam under pressure.

A further taxonomic characteristic of bacteria, which is of some importance in disease diagnosis and treatment, is based upon their staining reactions — specifically upon their response to the Gram staining technique. In this reaction, a basic dye (crystal violet) is first applied, then a solution of iodine. All bacteria will be stained blue at this point. The cells are then treated with alcohol. Gram-positive bacteria retain the crystal violet-iodine complex and remain blue. Gram-negative cells are completely decolorized by the alcohol. A red counterstain is then applied so that the decolorized Gram-negative cells will take on a contrasting color. The basis of the differential Gram reaction lies in the structure of the cell wall. Another staining approach distinguishes acid-fast bacteria (which retain carbol-fuchsin dye even when decolorized by hydrochloric acid) from non-acid-fast bacteria. Capsule staining also can be used, but the Gram reaction is of primary importance. Table 1 shows which organisms are Gram negative and which are Gram positive.

TABLE 1. GRAM REACTION CATEGORIES OF BACTERIA

Gram-Positive	Gram-Negative
Actinomyces bovis	*Aerobacter aerogenes*
Bacillus anthracis	*Brucella abortus*
Clostridium butyricum	*Brucella suis*
Clostridium septicum	*Eberthella typhi*
Clostridium sordelli	*Escherichia coli*
Clostridium tetani	*Hemophilus pertussis*
Clostridium welchii	*Klebsiella pneumoniae*
Corynebacterium diphtheriae	*Neisseria gonorrheae*
Diplococcus pneumoniae	*Neisseria intracellularis*
Erysipelothrix muriseptica	*Pasteurella pestis*
Mycobacterium tuberculosis	*Proteus vulgaris*
Staphylococcus aureus	*Pseudomonas aeruginosa*
Streptococcus fecalis	*Salmonella enteriditis*
Streptococcus hemolyticus	*Shigella paradysenteriae*
Streptococcus lactis	*Vibrio comma*
Streptococcus salivarius	
Streptococcus viridans	

Fundamental Structure of Bacteria

For many years, before the concept of *recombinant DNA*, scientists postulated that bacteria were unicellular microbes. In more recent years, the unicellular structure and, notably, the unicellular behavior of bacteria has been subjected to serious questions by a number of scientists. As observed by Shapiro, "Investigators are finding that in many ways an individual bacterium is more analogous to a component cell of a multicellular organism than it is to a free-living autonomous organism." There is evidence that complex communities of bacteria hunt prey, sometimes leaving chemical trails for the guidance of thousands of individuals. Scientists have observed such bacterial communal activity in *Rhizobium* microorganisms that fix nitrogen in the roots of leguminous plants. See also **Nitrogen**. Some bacteria have been observed in distinct colonies in petri dishes, and it has also been observed that *photosynthetic* bacteria (*Cyanobacteria*) grow as connected chains or intertwined mats with definitive configurations. Such reconfigurations, obvious in numerous bacteria, project to some scientists a manifestation of DNA rearrangement. With reference to the most morphologically complex of all bacteria, Shapiro observes, "Their elaborate fruiting bodies rival those of fungi and slime molds and have long been an object of scientific curiosity." Much research along these lines has been conducted by Hans Reichenbach (Society for Biotechnological Research, Braunschweig) and other researchers at the Institute for Scientific Film (Göttingen, Germany). Shapiro poses an interesting question, "What practical value, if any, do these findings have?" They may serve as insights to researchers who are seeking ways to produce various biochemicals via genetically engineered bacteria, or to those scientists in the medical field who are seeking improved drugs for handling bacterial infections.

In a scholarly paper, Magasanik reviews the role of biological research into the genetics, biochemistry, and physiology of bacteria during the past four decades and stresses the importance of these efforts in learning more about cells of all types at the molecular level. Magasanik stresses the advantages of using bacteria in genetic studies, including in most instances their simple non-compartmentalized structures and the accessibility of their genetic material. The importance of studying *Escherichia coli* for over a half-century is reviewed. Of notable interest is Magasanik's observation, "Yet, less than 50 years ago, in 1954, Kluyver and Van Niel, two eminent microbiologists, found it necessary to devote five lectures at Harvard University to convince their audience that the study of microbes could make a major contribution to biology."

Bacterial Genetics. The deoxyribonucleic acid (DNA) of bacteria is predominantly located in masses of variable shape, nuclearbodies (nucleoplasm or genophore), unbounded by a nuclear membrane. Bacteria thus are classified as procaryoids, in contrast to higher organisms containing

nuclear membranes, the eucaryoids. In general, nongrowing, stationary-phase bacteria contain one nuclear body per cell, whereas exponentially growing, log-phase bacteria contain two or more nuclear bodies per cell. These nuclei are the sister products of a preceding nuclear division.

When bacteria are inoculated into growth medium, there is a delay (lag phase) before division and exponential growth ensue. The rate of exponential growth is a characteristic of the bacterial strain, the temperature, and the nutritional environment. The amount of DNA per nuclear body remains constant at various growth rates, although cell mass and average number of nuclei per cell are functions of the growth rate.

Most of the genetic information of bacteria is contained in a single structure of fixed DNA content, a giant circular DNA molecule that replicates semi-conservatively. The enzymatic reactions involved in the biologically fundamental processes of DNA biosynthesis and genetic recombination are being elucidated in studies with bacterial systems.

Disease-Producing Bacteria

Bacterial diseases may be transmitted in a number of ways. The common respiratory diseases are distributed by small droplets of sputum and nasal secretions. Sexual intercourse is the method by which venereal diseases are usually spread. Further, since many bacteria live until they are dried, diseases may be transmitted through indirect contact with persons through objects they have handled. Some diseases are transmitted by water, milk, and foods that have become contaminated. Typhoid, cholera, and diarrheas are examples of diseases transmitted in the latter manner. Disease-producing bacteria usually cannot penetrate the unbroken skin: hence they enter by means of wounds, abrasions, or the natural openings of the body. See Table 2.

Increased Virulence of Bacteria. Evidence of the fact that bacterial diseases remain mysterious at the molecular level has surfaced in connection with a comparatively recent appearance of a notably virulent strain of group A streptococcus, which causes a new form of toxic shock–like syndrome (TSLS) that can cause the death of a patient within less than 24 hours after the first symptoms (mild skin infection or sore throat with mild cough) appear. A limited number of cases have been reported (1990–1991) in several countries, including Australia, Canada, England, Germany, New Zealand, and the United States. Apparently, the microorganism involved is the same as that which causes less threatening illnesses such as strep throat, impetigo, scarlet fever, and rheumatic fever.

Scientists have initially attributed this increased toxicity to a genetic "master switch" that moderates the toxicity of bacteria. Also, once again, the topic of bacterial "resistance" to antibiotics has been mentioned. Initial studies of TSLS were conducted by epidemiologists at the U.S. Centers of Disease Control, commencing with area studies embracing Alabama, Arizona, California, Colorado, Maryland, and Ohio. TSLS will be investigated from a genetic standpoint, just as such bacteria as *Escherichia coli* have been studied in the past. See also **Antibiotic**.

Certain staphylococci and mycoplasma generate enterotoxins and related proteins that cause food poisoning and shock. *Staphylococcus aureus*, in particular, causes an estimated 25% of food poisoning outbreaks in the United States. This bacterium also induces tampon-related toxic shock syndrome. Other *S. aureus*–related proteins (exfoliating toxins) are responsible for scaled skin syndrome. *S. pyogenes*–related toxins may cause fever, rash, and shock. The related *Mycoplasma arthriditis* also may produce shock.

The molecular (immunosuppressive) manner in which these bacteria perform, including genetic studies, is well described by Marrack and Kappler. As pointed out by these investigators, "Studies of staphylococcal enterotoxins and related proteins have provided scientists with rich and unexpected vision of the complex relationships between bacteria and their hosts, and have also yielded some insight into what might have been expected to be a totally unrelated subject, namely the T Cell Repertoire."

Bacterial Infections in Closely Confined Populations. A March 1989 study (U.S. Marine Corps recruits) of over 700 males reconfirmed the severe morbidity that *Streptococcus pyogenes* can produce. Persons who share crowded living conditions are at high risk for streptococcal infections, a fact that has been known for many years, but recently confirmed by a study. Earlier, the U.S. Navy reported over 1 million streptococcal infections of personnel during World War II, which resulted in over 21,000 cases of acute rheumatic fever and ranked second in terms of time lost due to illness. During that time frame, penicillin G benzathine was used, and, since then, this has been the drug of choice for preventing *S. pyogenes* infection. In the case of patients (approximately 7%) who are allergic to penicillin, oral erythromycin has been used.

Much was learned from the 1989 study reported by G.C. Gray et al. pertaining to improved dosage and other prophylactic methods used against *S. pyogenes*, especially in connection with high-risk populations. The study group observed that, "Relying on a system of passive clinical

TABLE 2. PRINCIPAL BACTERIAL DISEASES

Common Name of Disease	Medical Name of Disease	Bacteria Responsible	Body Region Involved	Incubation Period
Septic sore throat	Streptococcus sore throat (Tonsillitis)	*Streptococcus* (several species)	Throat and nasal membranes	3–5 days
Scarlet fever	Scarlatina	*Streptococcus scarlatinae*	Throat, tonsils, often other tissues	3–5 days
Pneumonia	Pneumococcal pneumonia	*Diplococcus pneumoniae*	Respiratory tract, including lungs	Varies
Spinal meningitis	Epidemic meningitis	*Diplococcus (Neisseria intracellularis)*	Respiratory tract, nervous system, sometimes blood	1–5 days
Clap	Gonorrhea	*Diplococcus (Neisseria gonorrhoeae)*	Reproductive organs	2–8 days
Typhoid and Paratyphoid fevers	Enteric fever	Short rod (*Salmonella typhosa; Salmonella paratyphi*)	Intestine	10–14 days
Bacillary dysentery	Shigellosis	Short rod (*Shigella dysenteriae*)	Intestine	1–4 days
Whooping cough	Pertussis	Small short rod (*Hemophilus pertussis*)	Respiratory tract	7–14 days
Bubonic plague	Pestis	Short rod (*Pasteurella pestis*)	Blood, spleen, liver, lymph nodes	2–10 days
Rabbit fever	Tularemia	Short rod (*Pasteurella tularensis*)	Lymph nodes, spleen, liver, kidneys, lungs	1–10 days
Undulant fever	Brucellosis	Short rod (*Brucella abortus*)	General body infection	5 days–10 weeks
Lockjaw	Tetanus	Sporeforming rod (*Clostridium tetani*)	Nervous system	2–40 days
Gas gangrene	Gas gangrene	Sporeforming rod (*Clostridium perfringens*)	Wounded areas	Varies
Botulinus	Botulism	Sporeforming rod (*Clostridium botulinum*)	Nervous system	18–66 hours
Tuberculosis	Tuberculosis	Irregular rod (*Mycobacterium tuberculosis*)	Lungs, bones, other organs	Varies
Syphilis	Lues	Spiral-shaped organism (*Treponema pallidum*)	Blood and nervous system	10–90 days
Diphtheria	Diphtheria	Irregular rod (*Corynebacterium diphtheriae*)	Respiratory tract	1–7 days

Note: Most of the diseases listed in this table are described in separate alphabetical entries in this book.

surveillance to prevent *S. pyogenes* epidemics is inadequate for high-risk groups." Further, it has been observed by Denny, "The implications of the study to civilians are less clear. . . . It is conceivable that streptococcal infection epidemics will occur in other settings that favor the close contact of susceptible hosts, such as day-care centers, summer camps, schools, colleges, and prisons. . . The lessons learned from infections among the marine recruits should be heeded."

The risk of infection is particularly high in the infant and toddler wards of hospitals. These patients have an immature immune system and lack a fully keratinized epidermis, as well as a fully developed mucosal barrier to infection. They have a decreased complement and reticulo-endothelial function, insufficient levels of serum immunoglobulins, and inadequate stores of white cells and a decreased ability to opsonize foreign antigens. Children that require prolonged hospitalization are at even higher risk. A further factor is the continuous contact of personnel who may tend to colonize pathogens and thus become a source of infection to the children. Crowded rooms with children, parents, and health care workers are common. One study has shown that 17% of preschool children hospitalized for more than a week develop respiratory viral illness. As described by Donowitz, "Hospital-acquired infections in children are clearly different. The host is highly susceptible both to the usual hospital pathogens and very importantly to common upper respiratory tract and gastrointestinal viruses. The risks of these infections are profound in children. They result in serious morbidity, mortality, and long-term physical, neurologic, and developmental sequelae."

Staphylococci (coagulase-negative) are found in the normal microflora of the skin and are generally considered non-threatening. This insipid role, however, may be altered in persons who have undergone certain medical procedures, such as intravascular catheters, peritoneal dialysis, joint protheses, cerebrospinal fluid shunts, and prosthetic heart valves. In such instances, coagulase-negative staphylococci may threaten bacteremia. These microorganisms also appear to contribute to increased bacteremia in newborn infants. In the past, these microorganisms have not been listed as a cause of sepsis in neonatal intensive care units. Recent data indicate a possible connection with the common use of an intravascular catheter. As observed by Klein, "Because parenteral lipids are an important source of sustenance for very small infants, their use should not be abandoned. Rather, the data should serve to accelerate efforts to gain further insight into the pathogenesis of bacteremia due to the development of techniques and materials that inhibit bacterial growth and the elaboration of slime within intravascular catheters."

Postoperative Wound Infections. Late 20th century (1991) statistics indicated that 1 of every 24 patients who had inpatient surgery (United States) had a postoperative wound infection. The single pathogen *Staphylococcus aureaus* caused over 35,000 of such infections each year. However, unexpected pathogens may be uncovered, including, in a 1979 incident, an outbreak of infections caused by *Legionella dumoffi* and *Rhodococcus bronchialis* pathogens, which normally grow slowly. Through the application of clever genetic procedures, it was learned that the rhodococcus was traceable to a an operating room nurse who owned two dogs whose neck scruff skin presented the rhodococcus. In such situations a patient may have to be returned to the operating room for debridement of infected tissue. In 1981, the Surgical Infection Society was formed to sponsor research in this field. Conferences of other groups, such as the annual Interscience Conference on Antimicrobial Agents and Chemotherapy have devoted meetings to pathogenesis and prevention of surgical-wound infection. Reference to articles by Kaiser (1991), Richet et al. (1991), and Lowry et al. (1991) is suggested for much more detail.

Chemical and Therapeutic Measures. In addition to the preventive measures described, for well over a century people have turned to chemical substances to assure clean environments and numerous drugs for treating bacterial infections once acquired.

A majority of bacteria may be killed by the action of chemical disinfectants. Sometimes a substance that prevents infection or inhibits the growth of microorganisms may be referred to as an antiseptic. Over the years, phenol and related compounds have proven effective when used with care (to avoid chemical injury). Free chlorine gas is an excellent disinfectant, as are the hypochlorites, for use in sterilizing structures. Tincture of iodine used on some cuts and other wounds has good disinfecting power, as does hydrogen peroxide in some cases, but these materials should be used with professional guidance. At one time, a number of mercury-containing compounds were used effectively and widely prior to environmental concerns associated with the element mercury. Also check **Microbial Agents** in the Alphabetical Index.

There has been much emphasis during the last few decades on *bacteriostatic* agents, which prevent or slow down the rate of bacterial growth and reproduction, so that the natural protective mechanisms of the body can overcome the infection. These chemicals include the sulfonamide group, such as sulfathiazole, sulfadiazine, sulfanilamide, sulfasuxidine, and sulfaguanidine. Although valuable in the treatment of certain diseases, the drugs should not be taken indiscriminately, nor in conjunction with bactericidal agents. See also **Sulfonamide Drugs**.

Antibiotics, which are produced by other living organisms, inhibit the growth of bacteria or destroy them (bactericidal). There are few known bacterial diseases, the effects of which cannot be mitigated if the proper antibiotic is used early in the course of the disease. Tetanus and botulism are exceptions. These diseases are the manifestation of extremely potent toxins produced by the bacteria, rather than symptoms caused by infections of the microorganisms themselves. See also **Antibiotic**.

Remarkable Survivability of Some Bacteria

Plastic pipes, even when flushed out with the most powerful disinfectants and germicides, have proven to be safe havens for some bacterial strains. Bacteria-resistant piping is of major importance in pharmaceutical manufacture. Research is underway to find plastic piping that will reject the adhesion of bacterial slimes. Currently, alloy steels are widely used. The adherence of slimes to plastic pipes permits colonies of bacteria to multiply. A similar problem exists when patients are furnished with plastic implants or prostheses. Hospital water supplies must be continuously monitored.

Prions

Sometimes difficult to distinguish from bacteria, fungi, viroids, and viruses, prions are infectious pathogens that cause a number of diseases of a neurologic dysfunctional nature, including scrapie in sheep and cattle and Creutzfeldt-Jakob disease, among other serious illnesses.

See **Creutzfeldt-Jakob Disease and Related Diseases**.

Beneficial Bacteria

As with insects — of which there are numerous species that are damaging to life processes (crop infestation, human discomfort, etc.), but also many that are beneficial (honeybee, lady beetle, etc.) — so are there both helpful and harmful bacteria. Bacteria play a major and constructive role in numerous processes that support life, such as food digestion and synthesis of vitamins. They serve as a basis for manufacturing antibiotics and as tools of genetic research. This list easily could be expanded a thousandfold. Some of the lesser-known examples are cited here.

Oil-Eating Bacteria. For several years, studies have been conducted to determine the ability of specialized bacteria. Some of these microorganisms are capable of converting oil into fatty acids, the result of which makes the oil products more water-soluble. Special strains have been grown by oceanologists at the University of Texas. These bacteria were tested in connection with the oil slick in the Gulf of Mexico after a supertanker (Mega Borg) spilled nearly 4 million tons of crude oil. Tests with other bacteria were tested earlier in connection with the Exxon Valdez spill in Alaska. See **Water Pollution**.

Bifidobacterium in Food Products. Commonly referred to as bifidobacteria, these microorganisms were discovered by Tissier (Pasteur Institute) in 1900 in the feces of infants. These bacteria are not true lactic acid bacteria, such as *Lactococcus* or *Pediococcus*, because they produce both acetic and lactic acids. Early research was difficult because of the lack of effective laboratory procedures. Considerable research since the mid-1950s, however, has been conducted. Hughes and Hoover (University of Delaware) reported in 1991 on the beneficial qualities of bifidobacteria and the possibility of their use in "Bifid"-amended food products, notably dairy products. These therapeutic effects include:

1. Maintenance of normal intestinal microflora balance;
2. Improvement of lactose tolerance of milk products;
3. Anti-tumorigenic activity;
4. Reduction of serum cholesterol levels; and
5. Synthesis of B-complex vitamins.

Products fermented with the bifid culture have a mild acidic flavor, similar to that of yogurt. A bifidus milk was developed for therapeutic use as early as the 1940s. By the 1960s it was found that it was possible to positively

modify intestinal flora with bifidum cultures. By the late 1980s, in Japan, it was found that yogurt sales nearly doubled with bifid-containing products. Similar increases in popularity occurred in France. As of the early 1990s, bifidus products are marketed in Brazil, Canada, England, Italy, Poland, and some of the Balkan countries. Because of health benefits and a good track record in other countries, no major barriers for expanding its use in the United States are foreseen by the experts.

Archaebacteria

Sometimes referred to as the "Third Kingdom of Life," the archaebacteria differ markedly from other bacteria. In fact, most scientists do not consider this form of life as a bacterium in any sense. The topic is included here because the association with bacteria is often made, since this microorganism has been misnamed, and most readers seeking information on it would most likely turn to this topic initially.

The archaebacteria were discovered by Woese (Univ. of Illinois, Urbana) as recently as 1977. These microorganisms differ markedly from eukaryotes, which have visible nuclei and are found in plants and animals, and differ as well from prokaryotes, which principally are found in bacteria and blue-green algae. See also **Cell (Biology)**; and **Genes and Genetics**.

In the area of a volcano, one may observe hot muds and polluted areas of water and air and quickly reach the conclusion that no life could possibly be present in such an environment. But microbial forms of life may be present, as typified by archaebacteria, which resemble ordinary bacteria, but which some scientists suggest may be another form of living material. There are numerous species of *Archaebacterium*, including: (1) *thermophiles*, which can survive up to temperatures of boiling water and greater; (2) *halophiles*, which tolerate extremely salty substances (greater, for example, than would be encountered in the Dead Sea); (3) *acidophiles*, one species that accommodates great acidity (ph = 1) and high temperatures (96 °C) and is aptly named *Acidanus infernus*, and (4) barophiles, which can withstand tremendous deep-sea pressures and simulated laboratory pressures (Scripps Institution of Oceanography) up to 1300 to 1400 atmospheres. It is interesting to note that acidophiles maintain their interiors at a neutral pH of 7.0, the mechanism of which remains to be discovered. In fact, the manner in which these organisms alter their molecular structure to withstand such trying conditions thus far has defied logical explanation.

A scientist at the Woods Hole Oceanographic Institution observes that it is fortunate that deep-sea organisms can adapt to such extreme pressures — otherwise, dead plant and animal debris that falls to the ocean bottom probably would not decay. It is surmised that barophilic bacteria participate in recycling organic materials in the ocean.

To date, archaebacteria have been positively identified in volcanic areas, such as Iceland, Italy, and Yellowstone Park (U.S.), and in the vicinity of hydrothermal vents in deep oceanic depths. Limited research to date has been conducted by Woese, previously mentioned, by researchers in oceanology, and by Stretter (Univ. of Regensburg, Germany). Generally, it has been found that the growth of most species stops at about 110 °C, but that optimal growth occurs at about 100 °C. It has been surmised to date that these microorganisms convert various organic materials by combining C with H_2 to form methane (CH_4). Other species appear to combine S and H to form H_2S.

Some scientists currently forecast that research on the archaebacteria may lead to a better understanding of catalytic enzymes and, because of this property, lead to catalysts that can participate at higher temperatures and thus accelerate chemical reaction time.

BACTERIAL DISEASES. In 1900, infectious diseases — especially bacterial diseases — were the leading cause of morbidity and mortality, and diseases such as tuberculosis and pneumococcal infection were called

the "Captain of all these men of death". A series of factors that began in the 16th and 17th centuries and extended into the 20th century greatly influenced the frequency of infectious diseases. These factors included improvements in hygiene and sanitation, better housing and nutrition, and safer food and water; the technological advances of the 20th century include use of vaccines and antibiotics. It is important to emphasize that, particularly for bacterial diseases, any reduction in their frequency is multifactorial and related to both specific and nonspecific changes. For example, examination of the estimated and reported mortality for tuberculosis in England from 1700 to 1920 shows a peak around 1770 at a rate of 700 per 100,000 — carrying a nearly 1% chance per year of dying of tuberculosis. By 1920, the mortality rate had decreased to less than 50 per 100,000. This decline preceded the introduction of BCG and antituberculosis chemotherapy. Thus, factors such as improvements in nutrition, decreased crowding, and better hygiene and sanitation were major contributors to the reduction in the incidence of tuberculosis. As we approach the 21st century, bacterial diseases and infectious diseases in general are no longer the leading causes of death in the developed world, except for certain conditions (e.g. heart disease) which may have a significant infectious etiology, as is currently being discussed. Globally, however, the perspective is different. For example, in 1992, almost 20 million deaths were caused by infectious and parasitic diseases, which WHO estimates to have been the leading cause of death worldwide. Bacterial disease (e.g. tuberculosis and other respiratory and diarrhoeal diseases of bacterial etiology) accounted for more than half of these deaths.

Bacterial diseases are not static but include newly emerging diseases, re-emerging diseases that were once thought to be conquered, and diseases that show changes of antimicrobial resistance. For example, in the last two decades, bacterial diseases have been newly recognized, including Legionnaires' disease, toxic shock syndrome, Lyme disease, campylobacteriosis, *Escherichia coli* 0157:H7 infections, helicobacter infections associated with peptic ulcer disease, and *Bartonella* infections associated with cat scratch disease. Cholera is an example of a re-emerging disease in the Western hemisphere which, since 1991, has caused over a million cases and 10,000 deaths. Other diseases, such as meningococcal infections, *Salmonella enteritidis* infections associated with shelleggs, foodborne listeriosis, and tuberculosis have increased in frequency, in some instances in both the industrialized and developing world. Antimicrobial resistance, once thought to be primarily a problem of hospital-acquired infections, is also a particular problem among community-acquired infections. In the hospital, there are strains of enterococci and tuberculosis that are essentially untreatable with antimicrobials, and strains of *Staphylococcus aureus* that have become relatively resistant to vancomycin — the last effective antimicrobial for many of these strains. In the community, drug-resistant infections with pneumococci, salmonella, shigella, and gonococci have become important public health problems. For example, strains of *Shigella dysenteriae* 1A in parts of the developing world have become resistant to almost every oral antimicrobial agent. Many strains of multidrug-resistant pneumococci are only susceptible to vancomycin.

One final point involves the often, unexpected consequences of changes that either intentionally or unintentionally affect the frequency of bacterial diseases. In the latter part of the 19th century and into the 20th century, efforts were made to improve hygiene and sanitation in many parts of the developed world. In Germany, for example, with increases in the number of homes in Frankfurt-am-Main that were connected to sewers and water mains, the death rate from typhoid fever rapidly decreased. However, an unexpected impact of such improvements in hygiene and sanitation in the developed world resulted in postponement or prevention of the exposure of many parts of the population to poliomyelitis, creating a population susceptible to epidemics and paralytic disease at a later age. Thus, efforts to eliminate or eradicate one disease may have important implications for another.

Bacterial diseases remain an important cause of morbidity and mortality in both the developed and the developing world. The emergence of new and re-emergence of old bacterial diseases, and the development of antimicrobial resistance pose substantive challenges to public health. For most bacterial diseases, eradication is not likely and any plans for elimination are complicated by the characteristics of the disease and limitations in intervention.

Bacterial diseases may be transmitted in a number of ways. The common respiratory diseases are distributed by small droplets of sputum and nasal secretions. Sexual intercourse is the method by which venereal diseases are usually spread. Further, since many bacteria live until they are dried, diseases may be transmitted through indirect contact with persons through objects, which they have handled. Some Diseases transmitted by water, milk, and foods, which have become contaminate. Typhoid, cholera, and diarrheas are examples of diseases transmitted in the latter manner. Disease-producing bacteria usually cannot penetrate the unbroken skin: hence they enter by means of wounds, abrasions, or the natural opening of the body.

Principal Bacterial Diseases and Infections

Anthrax. An acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis*. Anthrax most commonly occurs in wild and domestic lower vertebrates (cattle, sheep, goats, camels, antelopes, and other herbivores), but it can also occur in humans when they are exposed to infected animals or tissue from infected animals. Anthrax spores can be produced in a dry form (for *biological warfare*) which may be stored and ground into particles. When inhaled by humans, these particles cause respiratory failure and death within a week.

Anthrax is most common in agricultural regions where it occurs in animals. Anthrax can be found globally. It is more common in developing countries or countries without veterinary public health programs. Certain regions of the world (South and Central America, Southern and Eastern Europe, Asia, Africa, the Caribbean, and the Middle East) report more anthrax in animals than others. When anthrax affects humans, it is usually due to an occupational exposure to infected animals or their products. Workers who are exposed to dead animals and animal products from other countries where anthrax is more common may become infected with *B. anthracis* (industrial anthrax). Anthrax in wild livestock has occurred in the United States.

Because anthrax is considered to be a potential agent for use in biological warfare, the Department of Defense (DoD) has begun mandatory vaccination of all active duty military personnel who might be involved in conflict. For information on the anthrax Vaccine Immunization Program see; *http://www.aomc.org/ComDiseases/Anthrax.html*

Anthrax infection can occur in three forms: cutaneous (skin), inhalation, and gastrointestinal. *B. anthracis* spores can live in the soil for many years, and humans can become infected with anthrax by handling products from infected animals or by inhaling anthrax spores from contaminated animal products. Anthrax can also be spread by eating undercooked meat from infected animals. It is rare to find infected animals in the United States.

Symptoms of disease vary depending on how the disease was contracted, but symptoms usually occur within 7 days.

Cutaneous: Most (about 95%) anthrax infections occur when the bacterium enters a cut or abrasion on the skin, such as when handling contaminated wool, hides, leather or hair products (especially goat hair) of infected animals. Skin infection begins as a raised itchy bump that resembles an insect bite but within 1–2 days develops into a vesicle and then a painless ulcer, usually 1–3 cm in diameter, with a characteristic black necrotic (dying) area in the center. Lymph glands in the adjacent area may swell. About 20% of untreated cases of cutaneous anthrax will result in death. Deaths are rare with appropriate antimicrobial therapy.

Inhalation: Initial symptoms may resemble a common cold. After several days, the symptoms may progress to severe breathing problems and shock. Inhalation anthrax is usually fatal.

Intestinal: The intestinal disease form of anthrax may follow the consumption of contaminated meat and is characterized by an acute inflammation of the intestinal tract. Initial signs of nausea, loss of appetite, vomiting, fever are followed by abdominal pain, vomiting of blood, and severe diarrhea. Intestinal anthrax results in death in 25% to 60% of cases.

Prevention

In countries where anthrax is common and vaccination levels of animal herds are low, humans should avoid contact with livestock and animal products and avoid eating meat that has not been properly slaughtered and cooked. Also, an anthrax vaccine has been licensed for use in humans. The vaccine is reported to be 93% effective in protecting against anthrax.

The anthrax vaccine is manufactured and distributed by BioPort, Corporation, Lansing, Michigan. The vaccine is a cell-free filtrate vaccine, which means it contains no dead or live bacteria in the preparation. The final product contains no more than 2.4 mg of aluminum hydroxide as adjuvant. Anthrax vaccines intended for animals should not be used in

humans. The vaccine is US Food and Drug Administration (FDA)-licensed and has been routinely given in the US since 1970.

The Advisory Committee on Immunization Practices has recommend anthrax vaccination for the following groups:

- Persons who work directly with the organism in the laboratory.
- Persons who work with imported animal hides or furs in areas where standards are insufficient to prevent exposure to anthrax spores.
- Persons who handle potentially infected animal products in high-incidence areas. (Incidence is low in the United States, but veterinarians who travel to work in other countries where incidence is higher should consider being vaccinated.)
- Military personnel deployed to areas with high risk for exposure to the organism (as when it is used as a biological warfare weapon).

Pregnant women should be vaccinated only if absolutely necessary.

The immunization consists of three subcutaneous injections given 2 weeks apart followed by three additional subcutaneous injections given at 6, 12, and 18 months. Annual booster injections of the vaccine are recommended thereafter.

Like all vaccines, anthrax vaccine may cause soreness, redness, itching, swelling, and lumps at the injection site. About 30% of men and 60% of women report these local reactions, but they usually last only a short while. Lumps can persist a few weeks, but eventually disappear. Injection-site problems occur about twice as often among women. For both genders, between 1% and 5% report reactions at the injection site of 1 to 5 inches (2.54 to 12.7 centimeters) in diameter. Larger reactions at the injection site occur in about one in a hundred vaccine recipients. Beyond the injection site, from 5% up to 35% will notice muscle aches, joint aches, headaches, rash, chills, fever, nausea, loss of appetite, malaise, or related symptoms. Again, these symptoms usually go away after a few days. Serious events, such as those requiring hospitalization, are rare. They happen about once per 50,000 doses. Severe allergic reactions can occur after any vaccination, less than once per 100,000 doses. A moderate local reaction can occur if the vaccine is given to anyone with a past history of anthrax infection. Acute symptoms have varied, depending on the vaccine lot used. The most common side effects reported are: mild discomfort (localized swelling and redness at the site of injection), joint aches, and in a few cases, nausea, loss of appetite, and headaches. See also **Anthrax**.

Aspergillosis. Invasive pulmonary infection and disseminated disease, usually with fever, cough, hemoptysis, and chest pain. Allergic bronchopulmonary disease presents as asthma with cough and inspiratory stridor. Sinusitis with fever, localized pain. Rarely, cutaneous wound infection.

The cause or origin is *Aspergillus fumigatus*, and *Aspergillus flavus*. Less commonly *A. niger, A. terreus, A. nidulans*.

Inhalation of airborne fungal conidia (pulmonary and disseminated infection); fungus may colonize respiratory tract, complicating chronic lung disease. Exogenous infection may be associated with dust exposure (building renovation/construction). Rarely, nosocomial infection is postsurgical, at central catheter sites or burn wounds (primary cutaneous disease). See also **Aspergillosis**; and **Aspergillus**.

Bacterial Meningitis. See Meningococcal Disease (Meningitis).

Blastomycosis. Disease most commonly presents with subacute pneumonia; also can present as acute pneumonia, or as disseminated extrapulmonary form, commonly affecting the skin, bone, and genitourinary tract. Rarely affects the meninges.

The cause or origin is a systemic fungus (mycotic) disease caused by the dimorphic fungus *Blastomyces dermatitidis*.

Inhalation of airborne conidia (spores) after disturbance of contaminated soil, primarily soil in wooded areas and along waterways. In the United States disease is endemic in restricted geographic areas of the Ohio and Mississippi river valleys and southeastern states. See also **Blastomycosis**.

Botulism. A rare but serious paralytic illness caused by a nerve toxin that is produced by the bacterium *Clostridium botulinum*. There are three main kinds of botulism. Foodborne botulism is caused by eating foods that contain the botulism toxin. Wound botulism is caused by toxin produced from a wound infected with *Clostridium botulinum*. Infant botulism is caused by consuming the spores of the botulinum bacteria, which then grow in the intestines and release toxin. All forms of botulism can be fatal and are considered medical emergencies. Foodborne botulism can be especially dangerous because many people can be poisoned by eating a contaminated food.

Clostridium botulinum is the name of a group of bacteria commonly found in soil. These rod-shaped organisms grow best in low oxygen conditions. The bacteria form spores, which allow them to survive in a dormant state, until exposed to conditions that can support their growth. There are seven types of botulism toxin designated by the letters A through G; only types A, B, E and F cause illness in humans.

In the United States an average of 110 cases of botulism are reported each year. Of these, approximately 25% are foodborne, 72% are infant botulism, and the rest are wound botulism. Outbreaks of foodborne botulism involving two or more persons occur most years and usually caused by eating contaminated home-canned foods. The number of cases of foodborne and infant botulism has changed little in recent years, but wound botulism has increased because of the use of black-tar heroin, especially in California. See also **Foodborne Diseases**.

The classic symptoms of botulism include double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness. Infants with botulism appear lethargic, feed poorly, are constipated, and have a weak cry and poor muscle tone. These are all symptoms of the muscle paralysis caused by the bacterial toxin. If untreated, these symptoms may progress to cause paralysis of the arms, legs, trunk and respiratory muscles. In foodborne botulism, symptoms generally begin 18 to 36 hours after eating a contaminated food, but they can occur as early as 6 hours or as late as 10 days.

Physicians may consider the diagnosis if the patient's history and physical examination suggest botulism. However, these clues are usually not enough to allow a diagnosis of botulism. Other diseases such as Guillain-Barré syndrome, stroke, and myasthenia gravis can appear similar to botulism, and special tests may be needed to exclude these other conditions. These tests may include a brain scan, spinal fluid examination, nerve conduction test (electromyography, or EMG), and a tensilon test for myasthenia gravis. The most direct way to confirm the diagnosis is to demonstrate the botulinum toxin in the patient's serum or stool by injecting serum or stool into mice and looking for signs of botulism. The bacteria can also be isolated from the stool of persons with foodborne and infant botulism. These tests can be performed at some state health department laboratories and the Centers for Disease Control and Prevention (CDC).

The respiratory failure and paralysis that occur with severe botulism may require a patient to be on a breathing machine (ventilator) for weeks, plus intensive medical and nursing care. After several weeks, the paralysis slowly improves. If diagnosed early, foodborne and wound botulism can be treated with an antitoxin which blocks the action of toxin circulating in the blood. This can prevent patients from worsening, but recovery still takes many weeks. Physicians may try to remove contaminated food still in the gut by inducing vomiting or by using enemas. Wounds should be treated, usually surgically, to remove the source of the toxin-producing bacteria. Good supportive care in a hospital is the mainstay of therapy for all forms of botulism. Currently, antitoxin is not routinely given for treatment of infant botulism.

Botulism can result in death due to respiratory failure. However, in the past 50 years the proportion of patients with botulism who die has fallen from about 50% to 8%. A patient with severe botulism may require a breathing machine as well as intensive medical and nursing care for several months. Patients who survive an episode of botulism poisoning may have fatigue and shortness of breath for years and long-term therapy may be needed to aid recovery.

Botulism can be prevented. Foodborne botulism has often been from home-canned foods with low acid content, such as asparagus, green beans, beets and corn. However, outbreaks of botulism from more unusual sources such as chopped garlic in oil, chile peppers, tomatoes, improperly handled baked potatoes wrapped in aluminum foil, and home-canned or fermented fish. Persons who do home canning should follow strict hygienic procedures to reduce contamination of foods. Oils infused with garlic or herbs should be refrigerated. Potatoes, which have been baked, while wrapped in aluminum foil should be kept hot until served or refrigerated. Because the botulism toxin is destroyed by high temperatures, persons who eat home-canned foods should consider boiling the food for 10 minutes before eating it to ensure safety. Instructions on safe home canning can be obtained from county extension services or from the US Department of Agriculture. Because honey can contain spores of *Clostridium botulinum* and this has been a source of infection for infants, children less than 12 months old should not be fed honey. Honey is safe for persons 1 year of age and older. Wound botulism can be prevented by promptly seeking medical care for infected wounds and by not using injectable street drugs.

Public education about botulism prevention is an ongoing activity. Information about safe canning is widely available for consumers. State health departments and CDC have persons knowledgeable about botulism available to consult with physicians 24 hours a day. If antitoxin is needed to treat a patient, it can be quickly delivered to a physician anywhere in the country. Suspected outbreaks of botulism are quickly investigated, and if they involve a commercial product, the appropriate control measures are coordinated among public health and regulatory agencies. Physicians should report suspected cases of botulism to a state health department.

For information and guidelines on canning foods at home: USDA Home Canning Guide at: *http://edis.ifas.ufl.edu/scripts/htmlgen.exe?MENU HE:HOME CANNING GUIDE*

Brainerd Diarrhea. Brainerd diarrhea is a syndrome of acute onset of watery diarrhea (3 or more loose stools per day) lasting 4 weeks or longer, which can occur in outbreaks or as sporadic cases. It is named after Brainerd, Minnesota, the town where the first outbreak occurred in 1983. Patients typically experience 10–20 episodes per day of explosive, watery diarrhea, characterized by urgency and often by fecal incontinence. Accompanying symptoms include gas, mild abdominal cramping, and fatigue. Nausea, vomiting, and systemic symptoms such as fever are rare, although many patients experience slight weight loss. Despite extensive clinical and laboratory investigations, the cause of Brainerd diarrhea has not yet been identified. Although it is thought to be an infectious agent, intensive searches for bacterial, parasitic, and viral pathogens have been unsuccessful so far. The possibility remains that Brainerd diarrhea is caused by a chemical toxin, but no such toxin has yet been found.

Because the etiologic agent is unknown, there are no laboratory tests that can confirm the diagnosis. Brainerd diarrhea should be suspected in any patient who presents with the acute onset of nonbloody diarrhea lasting for more than 4 weeks, and for whom stool cultures and examinations for ova and parasites have been negative. Care should be taken to exclude other causes of chronic diarrhea, both infectious and noninfectious (e.g., lymphocytic colitis, collagenous colitis, tumors, drug reactions). Brainerd diarrhea is not characterized by any specific laboratory abnormalities. On colonoscopy, petechiae, aphthous ulcers and erythema may be observed. Microscopic examination of colonic tissue biopsy specimens often reveals mild inflammation, with an increased number of lymphocytes, particularly in the ascending and transverse colon. The stomach and small intestine generally appear normal. See also **Colitis and Other Inflammatory Bowel Diseases**.

There is no known curative treatment for Brainerd diarrhea. A variety of antimicrobial agents have been tried without success, including trimethoprim-sulfamethoxazole, ciprofloxacin, doxycycline, ampicillin, metronidazole, and paromomycin. Neither has there been any response to steroids or antiinflammatory agents. Approximately 50% of patients report some relief in symptoms with high doses of opioid antimotility drugs, such as loperamide, diphenoxylate, and paregoric.

Brainerd diarrhea is a self-limited illness. Symptoms may last a year or more, and typically have a waxing and waning course. Long-term follow-up studies have shown complete resolution in virtually all patients by the end of 3 years. There have been no known cases of sequelae or relapse once the illness has completely resolved.

Seven outbreaks of Brainerd diarrhea have been reported since 1983. Six occurred in the United States, five of which were in rural settings. One outbreak occurred on a South American cruise ship based in the Galapagos Islands. The original Brainerd outbreak, which involved 122 persons, was the largest outbreak. An outbreak in Henderson County, Illinois, involved 72 persons; the Galapagos Islands outbreak involved 58. A survey of gastroenterologists suggested that many patients who are not associated with a recognized outbreak seek treatment for illness compatible with Brainerd diarrhea. Further work needs to be done to establish the incidence of sporadic cases of Brainerd diarrhea. In the original Brainerd outbreak, raw (unpasteurized) milk was implicated as the vehicle for disease transmission. Contaminated and inadequately chlorinated or unboiled water has been identified as a source of Brainerd diarrhea in several other outbreaks. For example, illness was strongly associated with drinking untreated well water in the Henderson County outbreak. Persons who drank the same water after it was boiled did not get sick. Contaminated water was also implicated in the Galapagos Island outbreak. The diarrheal illness does not spread contagiously from one person to the next.

Avoiding drinking raw (unpasteurized) milk and water that has not been properly chlorinated or boiled will help reduce the risk for Brainerd diarrhea and many other diseases. Once the cause of Brainerd diarrhea is identified, more specific prevention measures can be formulated. See also **Diarrhea**.

Brucellosis. An infectious disease caused by the bacteria of the genus *Brucella*. These bacteria are primarily passed among animals, and they cause disease in many different vertebrates. Various Brucella species affect sheep, goats, cattle, deer, elk, pigs dogs, and several other animals. Humans become infected by coming in contact with animals or animal products that are contaminated with these bacteria. In humans brucellosis can cause a range of symptoms from mild flu-like illness to severe infection of the central nervous system or lining of the heart. It can also cause long-lasting or chronic symptoms that include recurrent fevers, joint pain, and depression.

Brucellosis is not very common in the United States, where 100 to 200 cases occur each year. But brucellosis can be very common in countries where animal disease control programs have not reduced the amount of disease among animals. Although brucellosis can be found worldwide, it is more common in countries that do not have good standardized and effective public health and domestic animal health programs. Areas currently listed as high risk are the Mediterranean Basin (Portugal, Spain, Southern France, Italy, Greece, Turkey, North Africa), South and Central America, Eastern Europe, Asia, Africa, the Caribbean, and the Middle East. Unpasteurized cheeses, sometimes called "village cheeses," from these areas may represent a particular risk for tourists.

Humans are generally infected in one of three ways: eating or drinking something that is contaminated with *Brucella*, breathing in the organism (inhalation), or having the bacteria enter the body through skin wounds. The most common way to be infected is by eating or drinking contaminated milk products. When sheep, goats, cows, or camels are infected, their milk is contaminated with the bacteria. If the milk is not pasteurized, these bacteria can be transmitted to persons who drink the milk or eat cheeses made it. Inhalation of *Brucella* organisms is not a common route of infection, but it can be important for those working in laboratories where the organism is cultured and could be inhaled by accident. Contamination of skin wounds may be a problem for persons working in slaughterhouses or meat packing plants or for veterinarians. Hunters may be infected through skin wounds or by accidentally ingesting the bacteria after cleaning deer, elk, moose, or wild pigs that they have killed.

Direct person-to-person spread of brucellosis is extremely rare. Mothers who are breast-feeding may transmit the infection to their infants. Sexual transmission has also been reported. For both sexual and breast-feeding transmission, if the infant or person at risk is treated for brucellosis, their risk of becoming infected will probably be eliminated within 3 days.

Do not consume unpasteurized milk, cheese, or ice cream while traveling. If you are not sure that the dairy product is pasteurized, don't eat it. Hunters and animal herdsman should use rubber gloves when handling viscera of animals. There is no vaccine available for humans. See also **Brucellosis**.

Campylobacteriosis. An infectious disease caused by bacteria of the genus *Campylobacter*. Most people who become ill with campylobacteriosis get diarrhea, cramping, abdominal pain, and fever within 2 to 5 days after exposure to the organism. The diarrhea may be bloody and can be accompanied by nausea and vomiting. The illness typically lasts 1 week. Some persons who are infected with *Campylobacter* do not have any symptoms at all. In persons with compromised immune systems, *Campylobacter* occasionally spreads to the bloodstream and causes a serious life-threatening infection.

Campylobacter is the most common bacterial cause of diarrheal illness in the United States. Virtually all cases occur as isolated, sporadic events, not as a part of large outbreaks. Even though surveillance is very limited, over 10,000 cases are reported to the Centers for Disease Control and Prevention (CDC) each year, equaling approximately six cases for each 100,000 persons in the population. Many more cases go undiagnosed or unreported, and campylobacteriosis is estimated to affect over 2 million persons every year, or 1% of the population. Campylobacteriosis occurs much more frequently in the summer months than in the winter. The organism is isolated from infants and young adults more frequently than from other age groups and from males more frequently than females. Although *Campylobacter* doesn't commonly cause death, it has been estimated that 500 persons with *Campylobacter* infections may die each year.

The *Campylobacter* organism is actually a group of spiral-shaped bacteria that can cause disease in humans and animals. Most human illness is caused by one species, called *Campylobacter jejuni*, but 1% of human *Campylobacter* cases are caused by other species. *Campylobacter jejuni* grows best at the body temperature of a bird, and seems to be well adapted to birds, who carry it without becoming ill. The bacterium is fragile. It cannot tolerate drying and can be killed by oxygen. It grows only if there is less than the atmospheric amount of oxygen present. Freezing reduces the number of *Campylobacter* bacteria present on raw meat.

Many different kinds of infections can cause diarrhea and bloody diarrhea. Doctors can look for bacterial causes of diarrhea by asking a laboratory to culture a sample of stool from an ill person. Diagnosis of *Campylobacter* requires special laboratory culture procedures, which doctors may need to specifically request.

Virtually all persons infected with *Campylobacter* will recover without any specific treatment. Patients should drink plenty of fluids as long as the diarrhea lasts. In more severe cases, antibiotics such as erythromycin or a fluoroquinolone can be used, and can shorten the duration of symptoms if they are given early in the illness.

Most people who get campylobacteriosis recover completely within 2 to 5 days, although sometimes recovery can take up to 10 days. Rarely, some long-term consequences can result from a *Campylobacter* infection. Some people may have arthritis following campylobacteriosis; others may develop a rare disease that affects the nerves of the body beginning several weeks after the diarrheal illness. This disease, called Guillain-Barré syndrome, occurs when a person's immune system is "triggered" to attack the body's own nerves, and can lead to paralysis that lasts several weeks and usually requires intensive care. It is estimated that approximately one in every 1000 reported campylobacteriosis cases leads to Guillain-Barré syndrome. As many as 40% of Guillain-Barré syndrome cases in this country may be triggered by campylobacteriosis.

Many chicken flocks are silently infected with *Campylobacter*; that is, the chickens are infected with the organism but show no signs of illness. *Campylobacter* can be easily spread from bird to bird through a common water source or through contact with infected feces. When an infected bird is slaughtered, *Campylobacter* can be transferred from the intestines to the meat. More than half of the raw chicken in the United States market has *Campylobacter* on it. *Campylobacter* is also present in the giblets, especially the liver.

Unpasteurized milk can become contaminated if the cow has an infection with *Campylobacter* in her udder or the milk is contaminated with manure. Surface water and mountain streams can become contaminated from infected feces from cows or wild birds. This infection is common in the developing world, and travelers to foreign countries are also at risk for becoming infected with *Campylobacter*.

There are some simple food handling practices for preventing *Campylobacter* infections. Physicians who diagnose campylobacteriosis and clinical laboratories that identify this organism should report their findings to the local health department. If many cases occur at the same time, it may mean that many people were exposed to a common contaminated food item or water source which might still be available to infect more people. When outbreaks occur, community education efforts can be directed at proper food handling techniques, especially thorough cooking of all poultry and other foods of animal origin, and common sense kitchen hygiene practices. Some data suggest that *Campylobacte*r can spread through a chicken flock in their drinking water. Providing clean, chlorinated water sources for the chickens might prevent *Campylobacter* infections in poultry flocks and thereby decrease the amount of contaminated meat reaching the market place.

Cholera. An acute, diarrheal illness caused by infection of the intestine with the bacterium *Vibrio cholerae*. The infection is often mild or without symptoms, but sometimes it can be severe. Approximately one in 20 infected persons has severe disease characterized by profuse watery diarrhea, vomiting, and leg cramps. In these persons, rapid loss of body fluids leads to dehydration and shock. Without treatment, death can occur within hours.

A person may get cholera by drinking water or eating food contaminated with the cholera bacterium. In an epidemic, the source of the contamination is usually the feces of an infected person. The disease can spread rapidly in areas with inadequate treatment of sewage and drinking water. The cholera bacterium may also live in the environment in brackish rivers and coastal waters. Shellfish eaten raw have been a source of cholera, and a few persons in the United States have contracted cholera after eating raw or undercooked shellfish from the Gulf of Mexico. The disease is not likely to spread directly from one person to another; therefore, casual contact with an infected person is not a risk for becoming ill.

The risk for cholera is very low for U.S. travelers visiting areas with epidemic cholera. When simple precautions are observed, contracting the disease is unlikely.

All travelers to areas where cholera has occurred should observe the following recommendations:

- Drink only water that you have boiled or treated with chlorine or iodine. Other safe beverages include tea and coffee made with boiled water and carbonated, bottled beverages with no ice.
- Eat only foods that have been thoroughly cooked and are still hot, or fruit that you have peeled yourself.
- Avoid undercooked or raw fish or shellfish, including ceviche.
- Make sure all vegetables are cookedavoid salads.
- Avoid foods and beverages from street vendors.
- Do not bring perishable seafood back to the United States.

A simple rule of thumb is "Boil it, cook it, peel it, or forget it."

At the present time, the manufacture and sale of the only licensed cholera vaccine in the United States (Wyeth-Ayerst) has been discontinued. It has not been recommended for travelers because of the brief and incomplete immunity if offers. No cholera vaccination requirements exist for entry or exit in any country. Two recently developed vaccines for cholera are licensed and available in other countries (Dukoral®, Biotec AB and Mutacol®, Berna). Both vaccines appear to provide a somewhat better immunity and fewer side-effects than the previously available vaccine. However, neither of these two vaccines is recommended for travelers nor are they available in the United States.

Cholera can be simply and successfully treated by immediate replacement of the fluid and salts lost through diarrhea. Patients can be treated with oral rehydration solution, a prepackaged mixture of sugar and salts to be mixed with water and drunk in large amounts. This solution is used throughout the world to treat diarrhea. Severe cases also require intravenous fluid replacement. With prompt rehydration, fewer than 1% of cholera patients die. Antibiotics shorten the course and diminish the severity of the illness, but they are not as important as rehydration. Persons who develop severe diarrhea and vomiting in countries where cholera occurs should seek medical attention promptly. See also **Cholera**; and **Diarrhea**.

Coccidioidomycosis. See also **Coccidioidomycosis**.

Cryptococcosis. See also **Cryptococcosis**.

Diarrheagenic Escherichia coli (non-Shiga toxin-producing *E. coli*), is associated with watery or bloody diarrhea, abdominal cramps, with or without fever.

The cause or origin of *Escherichia coli* has different serotypes, categorized into four major groups according to virulence mechanisms: enterotoxigenic (ETEC); enteropathogenic (EPEC); enteroinvasive (EIEC); and enteroaggregative (EAgg EC). Other groups (e.g., diffusely adherent *E. coli*) are less well established as pathogens.

The rate of occurrence is unknown. Very few laboratories can identify these organisms. Enterotoxigenic *E. coli* are the most common cause of travelers' diarrhea and have caused several foodborne outbreaks in the United States. There are an estimated 79,420 cases of ETEC in the United States each year. EPEC and EIEC primarily infect children in the developing world. Enteroaggregative *E. coli* probably causes chronic diarrhea in HIV-infected patients. See also **Diarrhea**; and **Foodborne Diseases**.

Transmission is through food or water contaminated with human or animal feces. Person-to-person transmission may also occur, but is likely to be less common. International travelers are at greatest risk for ETEC infection, while EPEC and EIEC are most common among young children in the developing world. EAggEC are most common among immunocompromised persons.

Diphtheria. An acute infection caused by toxin-producing strains of *Corynebacterium diphtheriae*. Clinical features of Respiratory diphtheria, presents as a sore throat with low-grade fever and an adherent membrane of the tonsils, pharynx, or nose. Neck swelling is usually present in severe disease. Cutaneous diphtheria presents as infected skin lesions, which lack a characteristic appearance. Myocarditis, polyneuritis, and airway obstruction are common complications of respiratory diphtheria; death

occurs in 5%–10% of respiratory cases. Complications and deaths are much less frequent in incutaneous diphtheria.

In the pre-vaccine era, children were at highest risk for respiratory diphtheria. Recently, diphtheria has primarily affected adults in the sporadic cases reported in the U.S. and in the large outbreaks in Russia and New Independent States of the Former Soviet Union. Approximately 0.001 cases per 100,000 population in the U.S. since 1980; before the introduction of vaccine in the 1920s incidence was 100–200 cases per 100,000 population. Diphtheria remains endemic in developing countries. The countries of the former Soviet Union have reported >150,000 cases in an epidemic which began in 1990. See also **Diphtheria**.

***Escherichia coli* O157:H7**, is an emerging cause of foodborne illness. An estimated 73,000 cases of infection and 61 deaths occur in the United States each year. Person-to-person contact in families and child care centers is also an important mode of transmission. *E. coli* O157:H7 was first recognized as a cause of illness in 1982 during an outbreak of severe bloody diarrhea; the outbreak was traced to contaminated hamburgers. Since then, most infections have come from eating undercooked ground beef. Infection can also occur after drinking raw milk and after swimming in or drinking sewage-contaminated water.

E. coli O157:H7 is one of hundreds of strains of the bacterium *Escherichia coli*. Although most strains are harmless and live in the intestines of healthy humans and animals, this strain produces a powerful toxin and can cause severe illness. Consumers can prevent *E. coli* O157:H7 infection by thoroughly cooking ground beef, avoiding unpasteurized milk, and washing hands carefully. Because the organism lives in the intestines of healthy cattle, preventive measures on cattle farms and during meat processing are being investigated.

The *E. coli* O157:H7 infection is diagnosed by detecting the bacterium in the stool. Most laboratories that culture stool do not test for *E. coli* O157:H7, so it is important to request that the stool specimen be tested on sorbitol-MacConkey (SMAC) agar for this organism. All persons who suddenly have diarrhea with blood should get their stool tested for *E. coli* O157:H7.

Most persons recover without antibiotics or other specific treatment in 5–10 days. There is no evidence that antibiotics improve the course of disease, and it is thought that treatment with some antibiotics may precipitate kidney complications. Antidiarrheal agents, such as loperamide (Imodium), should also be avoided.

Prevention

Cook all ground beef and hamburger thoroughly. Because ground beef can turn brown before disease-causing bacteria are killed, use a digital instant-read meat thermometer to ensure thorough cooking. Ground beef should be cooked until a thermometer inserted into several parts of the patty, including the thickest part, reads at least 160 °F. Persons who cook ground beef without using a thermometer can decrease their risk of illness by not eating ground beef patties that are still pink in the middle.

Avoid spreading harmful bacteria in your kitchen. Keep raw meat separate from ready-to-eat foods. Wash hands, counters, and utensils with hot soapy water after they touch raw meat. Never place cooked hamburgers or ground beef on the unwashed plate that held raw patties. Wash meat thermometers in between tests of patties that require further cooking.

Drink only pasteurized milk, juice, or cider. Commercial juice with an extended shelf-life that is sold at room temperature (e.g. juice in cardboard boxes, vacuum sealed juice in glass containers) has been pasteurized, although this is generally not indicated on the label. Juice concentrates are also heated sufficiently to kill pathogens.

Wash fruits and vegetables thoroughly, especially those that will not be cooked. Children under 5 years of age, immunocompromised persons, and the elderly should avoid eating alfalfa sprouts until their safety can be assured. Methods to decontaminate alfalfa seeds and sprouts are being investigated.

Drink municipal water that has been treated with chlorine or other effective disinfectants.

Avoid swallowing lake or pool water while swimming. Make sure that persons with diarrhea, especially children, wash their hands carefully with soap after bowel movements to reduce the risk of spreading infection, and that persons wash hands after changing soiled diapers. Anyone with a diarrheal illness should avoid swimming in public pools or lakes, sharing baths with others, and preparing food for others. See also **Diarrhea**; and **Foodborne Diseases**.

Foodborne Infections. See also **Foodborne Diseases**.

Glanders (*Burkholderia mallei*). Glanders is an infectious disease that is caused by the bacterium *Burkholderia mallei*. The organism has been considered as a potential agent for biological warfare and of biological terrorism. Glanders is primarily a disease affecting horses, but it also affects donkeys, and mules and can be naturally contracted by goats, dogs, and cats. Human infection, although not seen in the United States since 1945, has occurred rarely and sporadically among laboratory workers and those in direct and prolonged contact with infected, domestic animals. Geographically, the disease is endemic in Africa, Asia, the Middle East, and Central and South America.

Glanders is transmitted to humans by direct contact with infected animals. The bacteria enter the body through the skin and through mucosal surfaces of the eyes and nose. The sporadic cases have been documented in veterinarians, horse caretakers, and laboratorians.

The symptoms of glanders depend upon the route of infection with the organism. The types of infection include localized, pus-forming cutaneous infections, pulmonary infections, bloodstream infections, and chronic suppurative infections of the skin. Generalized symptoms of glanders include fever, muscle aches, chest pain, muscle tightness, and headache. Additional symptoms have included excessive tearing of the eyes, light sensitivity, and diarrhea.

Localized infections: If there is a cut or scratch in the skin, a localized infection with ulceration will develop within 1 to 5 days at the site where the bacteria entered the body. Swollen lymph nodes may also be apparent. Infections involving the mucous membranes in the eyes, nose, and respiratory tract will cause increased mucus production from the affected sites.

Pulmonary infections: In pulmonary infections, pneumonia, pulmonary abscesses, and pleural effusion can occur. Chest X-rays will show localized infection in the lobes of the lungs.

Bloodstream infections: Glanders bloodstream infections are usually fatal within 7 to 10 days.

Chronic infections: The chronic form of glanders involves multiple abscesses within the muscles of the arms and legs or in the spleen or liver.

There is no vaccine available for glanders. In countries where glanders is endemic in animals, prevention of the disease in humans involves identification and elimination of the infection in the animal population. Within the health care setting, transmission can be prevented by using common blood and body fluid precautions.

Because human cases of glanders are rare, there is limited information about antibiotic treatment of the organism in humans. Sulfadiazine has been found to be an effective in experimental animals and in humans. *Burkholderia mallei* is usually sensitive to tetracyclines, ciprofloxacin, streptomycin, novobiocin, gentamicin, imipenem, ceftrazidime, and the sulfonamides. Resistance to chloramphenicol has been reported.

Group A Streptococcal (GAS) Disease. Group A streptococcus is a bacterium often found in the throat and on the skin. People may carry group A streptococci in the throat or on the skin and have no symptoms of illness. Most GAS infections are relatively mild illnesses such as “strep throat,” or impetigo. On rare occasions, these bacteria can cause other severe and even life-threatening diseases.

These bacteria are spread through direct contact with mucus from the nose or throat of persons who are infected or through contact with infected wounds or sores on the skin. Ill persons, such as those who have strep throat or skin infections, are most likely to spread the infection. Persons who carry the bacteria but have no symptoms are much less contagious. Treating an infected person with an antibiotic for 24 hours or longer generally eliminates their ability to spread the bacteria. However, it is important to complete the entire course of antibiotics as prescribed. It is not likely that household items like plates, cups, or toys spread these bacteria.

Infection with GAS can result in a range of symptoms:

- No illness
- Mild illness (strep throat or a skin infection such as impetigo)
- Severe illness (necrotizing faciitis, streptococcal toxic shock syndrome)

Severe, sometimes life-threatening, GAS disease may occur when bacteria get into parts of the body where bacteria usually are not found, such as the blood, muscle, or the lungs. These infections are termed “invasive GAS disease.” Two of the most severe, but least common,

forms of invasive GAS disease are necrotizing fasciitis and Streptococcal Toxic Shock Syndrome. Necrotizing fasciitis (occasionally described by the media as "the flesh-eating bacteria") destroys muscles, fat, and skin tissue. Streptococcal toxic shock syndrome (STSS), causes blood pressure to drop rapidly and organs (e.g., kidney, liver, lungs) to fail. STSS is not the same as the "toxic shock syndrome" frequently associated with tampon usage. About 20% of patients with necrotizing fasciitis and more than half with STSS die. About 10%–15% of patients with other forms of invasive group A streptococcal disease die.

Invasive GAS infections occur when the bacteria get past the defenses of the person who is infected. This may occur, when a person has sores or other breaks in the skin, that allow the bacteria to get into the tissue, or when the person's ability to fight off the infection is decreased because of chronic illness, or an illness that affects the immune system. Also, some virulent strains of GAS are more likely to cause severe disease than others. Few people who come in contact with GAS will develop invasive GAS disease. Most people will have a throat or skin infection, and some may have no symptoms at all. Although healthy people can get invasive GAS disease, people with chronic illnesses like cancer, diabetes, and kidney dialysis, and those who use medications such as steroids have a higher risk.

About 10,000 cases of invasive GAS disease occurred in the United States in 1998. Of these, about 600 were STSS and 800 were necrotizing fasciitis. In contrast, there are several million cases of strep throat and impetigo each year.

Early signs and symptoms of necrotizing fasciitis;

- Fever
- Severe pain and swelling
- Redness at the wound site

Early signs and symptoms of STSS;

- Fever
- Dizziness
- Confusion
- A flat red rash over large areas of the body

GAS infections can be treated with many different antibiotics. Early treatment may reduce the risk of death from invasive group A streptococcal disease. However, even the best medical care does not prevent death in every case. For those with very severe illness, supportive care in an intensive care unit may be needed. For persons with necrotizing fasciitis, surgery often is needed to remove damaged tissue.

The spread of all types of GAS infection can be reduced by good hand washing, especially after coughing and sneezing and before preparing foods or eating. Persons with sore throats should be seen by a doctor who can perform tests to find out whether the illness is strep throat. If the test result shows strep throat, the person should stay home from work, school, or day care until 24 hours after taking an antibiotic. All wounds should be kept clean and watched for possible signs of infection such as redness, swelling, drainage, and pain at the wound site. A person with signs of an infected wound, especially if fever occurs, should seek medical care. It is not necessary for all persons exposed to someone with an invasive group A strep infection (i.e. necrotizing fasciitis or strep toxic shock syndrome) to receive antibiotic therapy to prevent infection. However, in certain circumstances, antibiotic therapy may be appropriate. That decision should be made after consulting with your doctor.

Group B Streptococcal Disease (GBS). Group B streptococcus (GBS) is a type of bacterium that causes illness in newborn babies, pregnant women, the elderly, and adults with other illnesses, such as diabetes or liver disease. GBS is the most common cause of life-threatening infections in newborns.

GBS is the most common cause of sepsis (blood infection) and meningitis (infection of the fluid and lining surrounding the brain) in newborns. GBS is a frequent cause of newborn pneumonia and is more common than other, better known, newborn problems such as rubella, congenital syphilis, and spina bifida. Before prevention methods were widely used, approximately 8,000 babies in the United States would get GBS disease each year. One of every 20 babies with GBS disease dies from infection. Babies that survive, particularly those who have meningitis, may have long-term problems, such as hearing or vision loss or learning disabilities. In pregnant women, GBS can cause bladder infections, womb infections (amnionitis, endometritis), and stillbirth. Among men and among women who are not pregnant, the most common diseases caused by GBS are blood infections, skin or soft tissue infections, and pneumonia. Approximately 20% of men and nonpregnant women with GBS disease die of the disease. See also **Rubella (German measles)**; and **Syphilis**.

Many people carry GBS in their bodies but do not become ill. These people are considered to be "carriers." Adults can carry GBS in the bowel, vagina, bladder, or throat. One of every four or five pregnant women carries GBS in the rectum or vagina. A fetus may come in contact with GBS before or during birth if the mother carries GBS in the rectum or vagina. People who carry GBS typically do so temporarily — that is, they do not become lifelong carriers of the bacteria. Approximately one of every 100 to 200 babies whose mothers carry GBS develop signs and symptoms of GBS disease. Three-fourths of the cases of GBS disease among newborns occur in the first week of life ("early-onset disease"), and most of these cases are apparent a few hours after birth. Sepsis, pneumonia, and meningitis are the most common problems. Premature babies are more susceptible to GBS infection than full-term babies, but most (75%) babies who get GBS disease are full term. GBS disease may also develop in infants 1 week to several months after birth ("late-onset disease"). Meningitis is more common with late-onset GBS disease. Only about half of late-onset GBS disease among newborns comes from a mother who is a GBS carrier; the source of infection for others with late-onset GBS disease is unknown. Late-onset disease is very rare.

GBS disease is diagnosed when the bacterium is grown from cultures of sterile body fluids, such as blood or spinal fluid. Cultures take a few days to complete. GBS infections in both newborns and adults are usually treated with antibiotics (e.g., penicillin or ampicillin) given through a vein.

GBS carriage can be detected during pregnancy by taking a swab of both the vagina and rectum for special culture. Physicians who culture for GBS carriage during prenatal visits should do so late in pregnancy (35–37 weeks' gestation); cultures collected earlier do not accurately predict whether a mother will have GBS at delivery. A positive culture result means that the mother carries GBS — not that she or her baby will definitely become ill. Women who carry GBS should not be given oral antibiotics before labor because antibiotic treatment at this time does not prevent GBS disease in newborns. An exception to this is when GBS is identified in urine during pregnancy. GBS in the urine should be treated at the time it is diagnosed. Carriage of GBS, in either the vagina or rectum, becomes important at the time of labor and delivery — when antibiotics are effective in preventing the spread of GBS from mother to baby.

Most GBS disease in newborns can be prevented by giving certain pregnant women antibiotics through the vein during labor. Any pregnant woman who previously had a baby with GBS disease or who has a urinary tract infection caused by GBS should receive antibiotics during labor. Pregnant women who carry GBS should be offered antibiotics at the time of labor or membrane rupture. GBS carriers at highest risk are those with any of the following conditions:

- fever during labor
- rupture of membranes (water breaking) 18 hours or more before delivery
- labor or rupture of membranes before 37 weeks

Because women who carry GBS but do not develop any of these three complications have a relatively low risk of delivering an infant with GBS disease, the decision to take antibiotics during labor should balance risks and benefits. Penicillin is very effective at preventing GBS disease in the newborn and is generally safe. A GBS carrier with none of the conditions above has the following risks:

- 1 in 200 chance of delivering a baby with GBS disease if antibiotics are not given
- 1 in 4000 chance of delivering a baby with GBS disease if antibiotics are given
- 1 in 10 chance, or lower, of experiencing a mild allergic reaction to penicillin (such as rash)
- 1 in 10,000 chance of developing a severe allergic reaction — anaphylaxis — to penicillin. Anaphylaxis requires emergency treatment and can be life-threatening.

If a prenatal culture for GBS was not done or the results are not available, physicians may give antibiotics to women with one or more of the risk conditions listed above.

In spite of testing and antibiotic treatment, some babies still get GBS disease. Vaccines to prevent GBS disease are being developed. In the future, women who are vaccinated may make antibodies that cross the placenta and protect the baby during birth and early infancy.

***Haemophilus influenzae* Serotype b (Hib) Disease.** In the United States and other industrialized countries, more than one-half of *Haemophilus influenzae* serotype b (Hib) cases present as meningitis with fever, headache, and stiff neck. The remainder present as cellulitis, arthritis, or sepsis. In developing countries, Hib is the second leading cause of bacterial pneumonia deaths in children as well.

During 1980–1990, incidence was 40–100/100,000 children <5 yrs old in the United States. In 1995, since use of Hib conjugate vaccine, incidence is <2 cases /100,000 children. Hib remains a major cause of lower respiratory tract infections in infants and children in developing countries where vaccine is not widely used.

Hansen's Disease (*Leprosy*). This chronic infectious disease A bacillus, *Mycobacterium leprae*, usually affects the skin and peripheral nerves but has a wide range of possible clinical manifestations. Patients are classified as having paucibacillary or multibacillary Hansen's disease. Paucibacillary Hansen's disease is milder and characterized by one or more hypopigmented skin macules. Multibacillary Hansen's disease is associated with symmetric skin lesions, nodules, plaques, thickened dermis, and frequent involvement of the nasal mucosa resulting in nasal congestion and epistaxis.

An estimated 500,000 new Hansen's disease cases are identified each year, with about 300 of these occurring in the United States. Most cases come from 55 countries where disease continues to be endemic. In 1998, WHO listed those countries reporting the most cases as Bangladesh, Brazil, India, Indonesia, Myanmar, and Nigeria. Worldwide, 1–2 million persons are permanently disabled as a result of Hansen's disease. However, persons receiving antibiotic treatment or having completed treatment are considered free of active infection.

Although the mode of transmission of Hansen's disease remains uncertain, most investigators think that *M. leprae* is usually spread from person to person in respiratory droplets. See also **Leprosy**.

***Helicobacter pylori* Infections (*H. pylori*) Ulcer.** *Helicobacter pylori* (*H. pylori*) is a bacterium that lives on the lining of the stomach. Although we used to think that spicy food, acid, and stress were the major causes of ulcers, we now know that nine out of ten ulcers are caused by *H. pylori*. Medicines that reduce stomach acid may make you feel better, but your ulcer may come back. Here's the good news: Since most ulcers are caused by this bacterial infection, they can be cured with the right antibiotics.

Twenty-five million Americans suffer from ulcers. An ulcer is a sore or hole in the lining of the stomach or duodenum (the first part of the small intestine). People of any age can get an ulcer and women are affected just as often as men.

The most common ulcer symptom is gnawing or burning pain in the abdomen between the breastbone and the belly button. The pain often occurs when the stomach is empty, between meals and in the early morning hours, but it can occur at any other time. It may last from minutes to hours and may be relieved by eating food or taking antacids. Less common symptoms include nausea, vomiting, or loss of appetite. Sometimes ulcers bleed. If bleeding continues for a long time, it may lead to anemia with weakness and fatigue. If bleeding is heavy, blood may appear in vomit or bowel movements, which may appear dark red or black.

Your health care provider may choose to use any of the following tests to determine if your ulcer is caused by *H. pylori*.

- Blood tests: A blood test can confirm if you have *H. pylori*. To perform this test, your health care provider sends your blood sample to a lab.
- Breath tests: A breath test can determine if you are infected with *H. pylori*. In this test, you drink a harmless liquid and in less than 1 hour, a sample of your breath is tested for *H. pylori*.
- Endoscopy: Your health care provider may decide to perform an endoscopy. This is a test in which a small tube with a camera inside is inserted through the mouth and into the stomach to look for ulcers. During the endoscopy, small samples of the stomach lining can be obtained and tested for *H. pylori*.

If you have an ulcer, you should be tested for H. pylori, and if found to be infected, you should be treated with antibiotics. Antibiotics are the new cure for ulcers; therapy is 1–2 weeks of one or two antibiotics and a medicine that will reduce the acid in the stomach. This treatment is a dramatic medical advance because eliminating *H. pylori* with antibiotics means that there is a greater than 90% chance that the ulcer can be cured for good. Remember, it is very important to continue taking all of this medicine until it is gone, even when you begin to feel better. If you are having side effects that make it hard to take your medicine, talk to your health care provider. See also **Ulcer (Acid-Peptic Diseases)**.

Histoplasmosis. A disease caused by the fungus *Histoplasma capsulatum*. Its symptoms vary greatly, but the disease primarily affect the lungs. Occasionally, other organs are affected. This form of the disease is called disseminated histoplasmosis, and it can be fatal if untreated. Positive histoplasmin skin tests occur in as many as 80% of the people living in areas where *H. capsulatum* is common, such as the eastern and central United States. Infants, young children, and older persons, in particular those with chronic lung disease are at increased risk for severe disease. Disseminated disease is more frequently seen in people with cancer or AIDS.

H. capsulatum is found throughout the world and is endemic in certain areas of the United States. *H. capsulatum* grows in soil and material contaminated with bat or bird droppings. Spores become airborne when contaminated soil is disturbed. Breathing the spores causes infection. The disease is not transmitted from an infected person to someone else.

Most infected persons have no apparent ill effects. The acute, benign respiratory disease is characterized by respiratory symptoms, a general ill feeling, fever, chest pains, and a dry or nonproductive cough. Distinct patterns may be seen on a chest x-ray. Chronic lung disease resembles tuberculosis and can worsen over months or years. The disseminated form is fatal unless treated. Antifungal medications are used to treat severe cases of acute histoplasmosis and all cases of chronic and disseminated disease. Mild disease usually resolves without treatment. Past infection results in partial protection against ill effects if reinfected. See also **Histoplasmosis**.

Legionellosis: Legionnaire's Disease (LD) and Pontiac Fever. Legionellosis is an infection caused by the bacterium *Legionella pneumophila*. The disease has two distinct forms:

- Legionnaires' disease, the more severe form of infection which includes pneumonia, and
- Pontiac fever, a milder illness.

Legionnaires' disease acquired its name in 1976 when an outbreak of pneumonia occurred among persons attending a convention of the American Legion in Philadelphia. Later, the bacterium causing the illness was named *Legionella*. An estimated 8,000 to 18,000 people get Legionnaires' disease in the United States each year. Some people can be infected with the *Legionella* bacterium and have mild symptoms or no illness at all. Outbreaks of Legionnaires' disease receive significant media attention. However, this disease usually occurs as a single, isolated case not associated with any recognized outbreak. When outbreaks do occur, they are usually recognized in the summer and early fall, but cases may occur year-round. About 5% to 30% of people who have Legionnaires' disease die.

Patients with Legionnaires' disease usually have fever, chills, and a cough, which may be dry or may produce sputum. Some patients also have muscle aches, headache, tiredness, loss of appetite, and, occasionally, diarrhea. Laboratory tests may show that these patients' kidneys are not functioning properly. Chest X-rays often show pneumonia. It is difficult to distinguish Legionnaires' disease from other types of pneumonia by symptoms alone; other tests are required for diagnosis. Persons with Pontiac fever experience fever and muscle aches and do not have pneumonia. They generally recover in 2 to 5 days without treatment. The time between the patient's exposure to the bacterium and the onset of illness for Legionnaires' disease is 2 to 10 days; for Pontiac fever, it is shorter, generally a few hours to 2 days.

The diagnosis of legionellosis requires special tests not routinely performed on persons with fever or pneumonia. Therefore, a physician must consider the possibility of legionellosis in order to obtain the right tests. Several types of tests are available. The most useful tests detect the bacteria in sputum, find Legionella antigens in urine samples, or compare antibody levels to Legionella in two blood samples obtained 3 to 6 weeks apart.

People of any age may get Legionnaires' disease, but the illness most often affects middle-aged and older persons, particularly those who smoke cigarettes or have chronic lung disease. Also at increased risk are persons whose immune system is suppressed by diseases such as cancer, kidney failure requiring dialysis, diabetes, or AIDS. Those that take drugs that suppress the immune system are also at higher risk. Pontiac fever most commonly occurs in persons who are otherwise healthy.

Erythromycin is the antibiotic currently recommended for treating persons with Legionnaires' disease. In severe cases, a second drug, rifampin, may be used in addition. Other drugs are available for patients unable

to tolerate erythromycin. Pontiac fever requires no specific treatment. See also **Legionellosis**.

Leptospirosis. A bacterial disease that affects humans and animals. It is caused by bacteria of the genus *Leptospira*. In humans it causes a wide range of symptoms, and some infected persons may have no symptoms at all. Symptoms of leptospirosis include high fever, severe headache, chills, muscle aches, and vomiting, and may include jaundice (yellow skin and eyes), red eyes, abdominal pain, diarrhea, or a rash. If the disease is not treated, the patient could develop kidney damage, meningitis (inflammation of the membrane around the brain and spinal cord), liver failure, and respiratory distress. In rare cases death occurs. Many of these symptoms can be mistaken for other diseases. Leptospirosis is confirmed by laboratory testing of a blood or urine sample.

Outbreaks of leptospirosis are usually caused by exposure to water contaminated with the urine of infected animals. Many different kinds of animals carry the bacterium; they may become sick but sometimes have no symptoms. *Leptospira* organisms have been found in cattle, pigs, horses, dogs, rodents, and wild animals. Humans become infected through contact with water, food, or soil containing urine from these infected animals. This may happen by swallowing contaminated food or water or through skin contact, especially with mucosal surfaces, such as the eyes or nose, or with broken skin. The disease is not known to be spread from person to person.

Leptospirosis is treated with antibiotics, such as doxycycline or penicillin, which should be given early in the course of the disease. Intravenous antibiotics may be required for persons with more severe symptoms. Persons with symptoms suggestive of leptospirosis should contact a health care provider. See also **Leptospirosis**.

Listeriosis. A serious infection caused by eating food contaminated with the bacterium *Listeria monocytogenes*, has recently been recognized as an important public health problem in the United States. The disease affects primarily pregnant women, newborns, and adults with weakened immune systems. A person with listeriosis has fever, muscle aches, and sometimes gastrointestinal symptoms such as nausea or diarrhea. If infection spreads to the nervous system, symptoms such as headache, stiff neck, confusion, loss of balance, or convulsions can occur. Infected pregnant women may experience only a mild, flu-like illness; however, infections during pregnancy can lead to premature delivery, infection of the newborn, or even stillbirth.

In the United States, an estimated 2,500 persons become seriously ill with listeriosis each year. Of these, 500 die. At increased risk are:

- Pregnant women — They are about 20 times more likely than other healthy adults to get listeriosis. About one-third of listeriosis cases happen during pregnancy.
- Newborns – Newborns rather than the pregnant women themselves suffer the serious effects of infection in pregnancy.
- Persons with weakened immune systems
- Persons with cancer, diabetes, or kidney disease
- Persons with AIDS — They are almost 300 times more likely to get listeriosis than people with normal immune systems.
- Persons who take glucocorticosteroid medications
- The elderly

Healthy adults and children occasionally become infected with Listeria, but they rarely become seriously ill.

Listeria monocytogenes is found in soil and water. Vegetables can become contaminated from the soil or from manure used as fertilizer. Animals can carry the bacterium without appearing ill and can contaminate foods of animal origin such as meats and dairy products. The bacterium has been found in a variety of raw foods, such as uncooked meats and vegetables, as well as in processed foods that become contaminated after processing, such as soft cheeses and cold cuts at the deli counter. Unpasteurized (raw) milk or foods made from unpasteurized milk may contain the bacterium. Listeria is killed by pasteurization, and heating procedures used to prepare ready-to-eat processed meats should be sufficient to kill the bacterium; however, unless good manufacturing practices are followed, contamination can occur after processing.

The general guidelines recommended for the prevention of listeriosis are similar to those used to help prevent other foodborne illnesses, such as salmonellosis.

General recommendations:

- Thoroughly cook raw food from animal sources, such as beef, pork, or poultry.
- Wash raw vegetables thoroughly before eating.
- Keep uncooked meats separate from vegetables and from cooked foods and ready-to-eat foods.
- Avoid raw (unpasteurized) milk or foods made from raw milk.
- Wash hands, knives, and cutting boards after handling uncooked foods.

Recommendations for persons at high risk, such as pregnant women and persons with weakened immune systems, in addition to the recommendations listed above:

- Avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and
- Mexican-style cheese. (Hard cheesed, processed cheeses, cream cheese, cottage cheese, or yogurt need not be avoided.)
- Left-over foods or ready-to-eat foods, such as hot dogs, should be cooked until steaming hot before eating.
- Although the risk of listeriosis associated with foods from deli counters is relatively low, pregnant women and immunosuppressed persons may choose to avoid these foods or thoroughly reheat cold cuts before eating.

There is no routine screening test for susceptibility to listeriosis during pregnancy, as there is for rubella and some other congenital infections. If you have symptoms such as fever or stiff neck, consult your doctor. A blood or spinal fluid test (to cultivate the bacteria) will show if you have listeriosis. During pregnancy, a blood test is the most reliable way to find out if your symptoms are due to listeriosis. The risk of an individual person developing *Listeria* infection after consumption of a contaminated product is very small. If you have eaten a contaminated product and do not have any symptoms, it is recommend that you do not have any tests or treatment, even if you are in a high-risk group. However, if you are in a high-risk group, have eaten the contaminated product, and within 2 months become ill with fever or signs of serious illness, you should contact your physician and inform him or her about this exposure.

Government agencies and the food industry have taken steps to reduce contamination of food by the *Listeria* bacterium. The Food and Drug Administration and the U.S. Department of Agriculture monitor food regularly. When a processed food is found to be contaminated, food monitoring and plant inspection are intensified, and if necessary, the implicated food is recalled. The National Center for Infectious Diseases (NCID) is studying listeriosis in several states to help measure the impact of prevention activities and recognize trends in disease occurrence. NCID also assists local health departments in investigating outbreaks. Early detection and reporting of outbreaks of listeriosis to local and state health departments can help identify sources of infection and prevent more cases of the disease.

Melioidosis (*Burkholderia pseudomallei*). Melioidosis, also called Whitmore's disease, is an infectious disease caused by the bacterium *Burkholderia pseudomallei*. Melioidosis is clinically and pathologically similar to glanders disease, but the ecology and epidemiology of melioidosis are different from glanders. Melioidosis is endemic in Southeast Asia with the greatest concentration of cases reported in Vietnam, Cambodia, Laos, Thailand, Malaysia, Myanmar (Burma), and northern Australia. Additionally, it is seen in the South Pacific, Africa, India, and the Middle East. In many of these countries.

Burkholderia pseudomallei is so prevalent that it is a common contaminate found on laboratory cultures. Moreover, it has been a common pathogen isolated from troops of all nationalities that have served in areas with endemic disease. A few isolated cases of melioidosis have occurred in the Western Hemisphere in Mexico, Panama, Ecuador, Haiti, Brazil, Peru, Guyana, and in the states of Hawaii and Georgia. In the United States, confirmed cases range from none to five each year and occur among travelers and immigrants.

Besides humans, many animal species are susceptible to the bacteria causing melioidosis. These include sheep, goats, horses, swine, cattle, dogs, and cats. Transmission occurs by direct contact with contaminated soil and surface waters. In Southeast Asia, the organism has been repeatedly isolated from agriculture fields, with infection occurring primarily during the rainy season. Humans and animals are believed to acquire the infection by inhalation of dust, ingestion of contaminated water, and contact with contaminated soil especially through skin abrasions, and for military troops, by contamination of war wounds. Person-to-person transmission can occur.

Illness from melioidosis can be categorized as acute or localized infection, acute pulmonary infection, acute bloodstream infection, and chronic suppurative infection. Inapparent infections are also possible. The incubation period (time between exposure and appearance of clinical

symptoms) is not clearly defined, but may range from 2 days to many years.

- *Acute, localized infection*: This form of infection is generally localized as a nodule and results from inoculation through a break in the skin. The acute form of melioidosis can produce fever and general muscle aches, and may progress rapidly to infect the bloodstream.
- *Pulmonary infection*: This form of the disease can produce a clinical picture of mild bronchitis to severe pneumonia. The onset of pulmonary melioidosis is typically accompanied by a high fever, headache, anorexia, and general muscle soreness. Chest pain is common, but a nonproductive or productive cough with normal sputum is the hallmark of this form of melioidosis.
- *Acute bloodstream infection*: Patients with underlying illness such as HIV, renal failure, and diabetes are affected by this type of the disease, which usually results in septic shock. The symptoms of the bloodstream infection vary depending on the site of original infection, but they generally include respiratory distress, severe headache, fever, diarrhea, development of pus-filled lesions on the skin, muscle tenderness, and disorientation. This is typically an infection of short duration, and abscesses will be found throughout the body.
- *Chronic suppurative infection*: Chronic melioidosis is an infection that involves the organs of the body. These typically include the joints, viscera, lymph nodes, skin, brain, liver, lung, bones, and spleen.

There is no vaccine for melioidosis. Prevention of the infection in endemic-disease areas can be difficult since contact with contaminated soil is so common. Persons with diabetes and skin lesions should avoid contact with soil and standing water in these areas. Wearing boots during agricultural work can prevent infection through the feet and lower legs. In health care settings, using common blood and body fluid precautions can prevent transmission. Most cases of melioidosis can be treated with appropriate antibiotics.

Burkholderia pseudomallei, the organism that causes melioidosis, is usually sensitive to imipenem, penicillin, doxycycline, amoxycillin-clavulanic acid, azlocillin, ceftrazidime, ticarcillin-vulanic acid, ceftriaxone, and aztreonam. Treatment should be initiated early in the course of the disease. Although bloodstream infection with melioidosis can be fatal, the other types of the disease are nonfatal. The type of infection and the course of treatment can predict any long-term sequelae.

Meningitis. See Group B Streptococcal Disease (GBS); Haemophilus influenzae; Meningococcal Disease; and Streptococcus pneumoniae.

Meningococcal Disease. Meningitis is an infection of the fluid of a person's spinal cord and the fluid that surrounds the brain. People sometimes refer to it as spinal meningitis. Meningitis is usually caused by a viral or bacterial infection. Knowing whether meningitis is caused by a virus or bacterium is important because the severity of illness and the treatment differ. Viral meningitis is generally less severe and resolves without specific treatment, while bacterial meningitis can be quite severe and may result in brain damage, hearing loss, or learning disability. For bacterial meningitis, it is also important to know which type of bacteria is causing the meningitis because antibiotics can prevent some types from spreading and infecting other people. Before the 1990s, *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis, but new vaccines being given to all children as part of their routine immunizations have reduced the occurrence of invasive disease due to *H. influenzae*. Today, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the leading causes of bacterial meningitis.

High fever, headache, and stiff neck are common symptoms of meningitis in anyone over the age of 2 years. These symptoms can develop over several hours, or they may take 1 to 2 days. Other symptoms may include nausea, vomiting, discomfort looking into bright lights, confusion, and sleepiness. In newborns and small infants, the classic symptoms of fever, headache, and neck stiffness may be absent or difficult to detect, and the infant may only appear slow or inactive, or be irritable, have vomiting, or be feeding poorly. As the disease progresses, patients of any age may have seizures.

Early diagnosis and treatment are very important. If symptoms occur, the patient should see a doctor immediately. The diagnosis is usually made by growing bacteria from a sample of spinal fluid. The spinal fluid is obtained by performing a spinal tap, in which a needle is inserted into an area in the lower back where fluid in the spinal canal is readily accessible. Identification of the type of bacteria responsible is important for selection of correct antibiotics. Bacterial meningitis can be treated with a number of effective antibiotics. It is important, however, that treatment be started early in the course of the disease. Appropriate antibiotic treatment of most common types of bacterial meningitis should reduce the risk of dying from meningitis to below 15%, although the risk is higher among the elderly.

Some forms of bacterial meningitis are contagious. The bacteria are spread through the exchange of respiratory and throat secretions (i.e., coughing, kissing). Fortunately, none of the bacteria that cause meningitis are as contagious as things like the common cold or the flu, and they are not spread by casual contact or by simply breathing the air where a person with meningitis has been. However, sometimes the bacteria that cause meningitis have spread to other people who have had close or prolonged contact with a patient with meningitis caused by *Neisseria meningitidis* (also called meningococcal meningitis) or Hib. People in the same household or day-care center, or anyone with direct contact with a patient's oral secretions (such as a boyfriend or girlfriend) would be considered at increased risk of acquiring the infection. People who qualify as close contacts of a person with meningitis caused by *N. meningitidis* should receive antibiotics to prevent them from getting the disease. Antibiotics for contacts of a person with Hib meningitis disease are no longer recommended if all contacts 4 years of age or younger are fully vaccinated against Hib disease.

There are vaccines against Hib and many types of *Streptococcus pneumoniae*. The vaccines against Hib are very safe and highly effective. There is also a vaccine that protects against four strains of *N. meningitidis*, but it is not routinely used in the United States and is not effective in children under 18 months of age. The vaccine against *N. meningitidis* is sometimes used to control outbreaks of some types of meningococcal meningitis in the United States. Meningitis cases should be reported to state or local health departments to assure follow-up of close contacts and recognize outbreaks. Although large epidemics of meningococcal meningitis do not occur in the United States, some countries experience large, periodic epidemics. Overseas travelers should check to see if meningococcal vaccine is recommended for their destination. Travelers should receive the vaccine at least 1 week before departure, if possible. Information on areas for which meningococcal vaccine is recommended can be obtained by contacting the Centers for Disease Control and Prevention (CDC). A vaccine to prevent meningitis due to *S. pneumoniae* (also called pneumococcal meningitis) can also prevent other forms of infection due to *S. pneumoniae*. The pneumococcal vaccine is not effective in children under 2 years of age but is recommended for all persons over 65 years of age and younger persons with certain chronic medical problems. See also **Meningitis**.

Nocardiosis. Overall, 80% of cases present as invasive pulmonary infection, disseminated disease, or brain abscess; 20% present as cellulitis. For pulmonary diseases common symptoms are fever, cough, and chest pain; for central nervous system disease symptoms are usually headache, lethargy, confusion, seizures, and sudden onset of neurologic deficit. *Nocardia asteroides* (causes at least 50% of invasive infections). Other pathogenic species include *N. farcinica, N. nova, N. transvalensis, N. brasiliensis*, and *N. pseudobrasiliensis*.

In the United States, an estimated 500–1,000 new cases of *Nocardia* infection occur annually. An estimated 10%–15% of these patients also have HIV infection. Approximately 10% of cases with uncomplicated pneumonia are fatal. Case-fatality rate increases with overwhelming infection, disseminated disease, or brain abscess. Surgical drainage may be indicated and may improve patient outcome.

Pulmonary and disseminated infections occur through inhalation and primary cutaneous disease through soil-contaminated wounds. Rarely, nosocomial postsurgical transmission occurs. Risks may occur in severely immunocompromised persons (e.g., persons with malignancy, connective tissue disorders, bone marrow or solid organ transplantation, high-dose corticosteroid use, or HIV infection), alcoholism or pulmonary alveolar proteinosis, and males (ratio male:female = 3:1).

Although incidence data are extremely limited, the number of cases probably has increased recently because of the overall increased number of severely immunocompromised persons. Diagnosis may be difficult. In the clinical laboratory, routine cultures may be held for insufficient time to grow nocardiae, and referral to a reference laboratory may be needed for species identification. Recently, *N. farcinica* and *N. nova* have been removed from *N. asteroides* complex. *N. farcinica* frequently is more resistant to antimicrobial agents, including trimethoprim-sulfamethoxazole

(TMP-SMX) (the drug of choice), and has been shown to be more virulent in an animal model. TMP-SMX therapy for HIV-infected patients may be complicated by frequent occurrence of side effects and drug resistance. A new combination drug therapy (sulfonamide, ceftriaxone, and amikacin) has shown promise for infections difficult to treat. Application of newer molecular diagnostic and subtyping methods may assist in earlier diagnosis and outbreak investigation. In 1998 MSPB described a rapid PCR-based method to differentiate *N. farcinica* from other nocardiae.

Peptic Ulcer Disease. See: *Helicobacter pylori*. See also **Ulcer (Acid-Peptic Diseases)**.

Pertussis. See also **Pertussis (Whooping Cough)**.

Pneumonia. See also **Pneumonia**.

Psittacosis. See also **Psittacosis (Parrot fever)**.

***Salmonella enteritidis* Infection.** Egg-associated salmonellosis is an important public health problem in the United States and several European countries. A bacterium, *Salmonella enteritidis*, can be inside perfectly normal-appearing eggs, and if the eggs are eaten raw or undercooked, the bacterium can cause illness. During the 1980s, illness related to contaminated eggs occurred most frequently in the northeastern United States, but now illness caused by *S. enteritidis* is increasing in other parts of the country as well. Consumers should be aware of the disease and learn how to minimize the chances of becoming ill.

A person infected with the *Salmonella enteritidis* bacterium usually has fever, abdominal cramps, and diarrhea beginning 12 to 72 hours after consuming a contaminated food or beverage. The illness usually lasts 4 to 7 days, and most persons recover without antibiotic treatment. However, the diarrhea can be severe, and the person may be ill enough to require hospitalization.

The elderly, infants, and those with impaired immune systems may have a more severe illness. In these patients, the infection may spread from the intestines to the blood stream, and then to other body sites and can cause death unless the person is treated promptly with antibiotics.

Unlike eggborne salmonellosis of past decades, the current epidemic is due to intact and disinfected grade A eggs. *Salmonella enteritidis* silently infects the ovaries of healthy appearing hens and contaminates the eggs before the shells are formed.

Although most infected hens have been found in the northeastern United States, the infection also occurs in hens in other areas of the country. In the Northeast, approximately one in 10,000 eggs may be internally contaminated. In other parts of the United States, contaminated eggs appear less common. Only a small number of hens seem to be infected at any given time, and an infected hen can lay many normal eggs while only occasionally laying an egg contaminated with the *Salmonella* bacterium. See also **Foodborne Diseases**.

Salmonellosis. An infection with a bacteria called Salmonella. Most persons infected with Salmonella develop diarrhea, fever, and abdominal cramps 12 to 72 hours after infection. The illness usually lasts 4 to 7 days, and most persons recover without treatment. However, in some persons the diarrhea may be so severe that the patient needs to be hospitalized. In these patients, the Salmonella infection may spread from the intestines to the blood stream, and then to other body sites and can cause death unless the person is treated promptly with antibiotics. The elderly, infants, and those with impaired immune systems are more likely to have a severe illness.

The Salmonella germ is actually a group of bacteria that can cause diarrheal illness in humans. They are microscopic living creatures that pass from the feces of people or animals, to other people or other animals. There are many different kinds of Salmonella bacteria. Salmonella serotype Typhimurium and Salmonella serotype Enteritidis are the most common in the United States. Salmonella has been known to cause illness for over 100 years. They were discovered by a American scientist named Salmon, for whom they are named.

Many different kinds of illnesses can cause diarrhea, fever, or abdominal cramps. Determining that Salmonella is the cause of the illness depends on laboratory tests that identify Salmonella in the stools of an infected person. These tests are sometimes not performed unless the laboratory is instructed specifically to look for the organism. Once Salmonella has been identified, further testing can determine its specific type, and which antibiotics could be used to treat it.

Salmonella infections usually resolve in 5–7 days and often do not require treatment unless the patient becomes severely dehydrated or the infection spreads from the intestines. Persons with severe diarrhea may require rehydration, often with intravenous fluids. Antibiotics are not usually necessary unless the infection spreads from the intestines, then it can be treated with ampicillin, gentamicin, trimethoprim/sulfamethoxazole, or ciprofloxacin. Unfortunately, some Salmonella bacteria have become resistant to antibiotics, largely as a result of the use of antibiotics to promote the growth of feed animals.

Persons with diarrhea usually recover completely, although it may be several months before their bowel habits are entirely normal. A small number of persons who are infected with Salmonella, will go on to develop pains in their joints, irritation of the eyes, and painful urination. This is called *Reiter's syndrome*. It can last for months or years, and can lead to chronic arthritis, which is difficult to treat. Antibiotic treatment does not make a difference in whether or not the person later develops arthritis.

Prevention

There is no vaccine to prevent salmonellosis. Since foods of animal origin may be contaminated with Salmonella, people should not eat raw or undercooked eggs, poultry, or meat. Raw eggs may be unrecognized in some foods such as homemade hollandaise sauce, caesar and other salad dressings, tiramisu, homemade ice cream, homemade mayonnaise, cookie dough, and frostings. Poultry and meat, including hamburgers, should be well-cooked, not pink in the middle. Persons also should not consume raw or unpasteurized milk or other dairy products. Produce should be thoroughly washed before consuming.

Cross-contamination of foods should be avoided. Uncooked meats should be keep separate from produce, cooked foods, and ready-to-eat foods. Hands, cutting boards, counters, knives, and other utensils should be washed thoroughly after handling uncooked foods. Hand should be washed before handling any food, and between handling different food items.

People who have salmonellosis should not prepare food or pour water for others until they have been shown to no longer be carrying the Salmonella bacterium.

People should wash their hands after contact with animal feces. Since reptiles are particularly likely to have Salmonella, everyone should immediately wash their hands after handling reptiles. Reptiles (including turtles) are not appropriate pets for small children and should not be in the same house as an infant. See also **Foodborne Diseases**.

Shigellosis. An infectious disease caused by a group of bacteria called *Shigella*. Most who are infected with *Shigella* develop diarrhea, fever, and stomach cramps starting a day or two after they are exposed to the bacterium. The diarrhea is often bloody. Shigellosis usually resolves in 5 to 7 days. In some persons, especially young children and the elderly, the diarrhea can be so severe that the patient needs to be hospitalized. A severe infection with high fever may also be associated with seizures in children less than 2 years old. Some persons who are infected may have no symptoms at all, but may still pass the *Shigella* bacteria to others.

The *Shigella* germ is actually a family of bacteria that can cause diarrhea in humans. They are microscopic living creatures that pass from person to person. *Shigella* were discovered over 100 years ago by a Japanese scientist named Shiga, for whom they are named. There are several different kinds of *Shigella* bacteria: *Shigella sonnei*, also known as "Group D" *Shigella*, accounts for over two-thirds of the shigellosis in the United States. A second type, *Shigella flexneri*, or "group B" *Shigella*, accounts for almost all of the rest. Other types of Shigella are rare in this country, though they continue to be important causes of disease in the developing world. One type found in the developing world, *Shigella dysenteriae* type1, causes deadly epidemics there.

Many different kinds of diseases can cause diarrhea and bloody diarrhea, and the treatment depends on which germ is causing the diarrhea. Determining that *Shigella* is the cause of the illness depends on laboratory tests that identify *Shigella* in the stools of an infected person. These tests are sometimes not performed unless the laboratory is instructed specifically to look for the organism. The laboratory can also do special tests to tell which type of *Shigella* the person has and which antibiotics, if any, would be best to treat it.

Shigellosis can usually be treated with antibiotics. The antibiotics commonly used for treatment are ampicillin, trimethoprim/sulfamethoxazole (also known as Bactrim® or Septra®), nalidixic acid, or ciprofloxacin. Appropriate treatment kills the *Shigella* bacteria that might be present in the patient's stools, and shortens the illness. Unfortunately, some *Shigella*

bacteria have become resistant to antibiotics and using antibiotics to treat shigellosis can actually make the germs more resistant in the future. Persons with mild infections will usually recover quickly without antibiotic treatment. Therefore, when many persons in a community are affected by shigellosis, antibiotics are sometimes used selectively to treat only the more severe cases. Antidiarrheal agents such as loperamide (Imodium®) or diphenoxylate with atropine (Lomotil®) are likely to make the illness worse and should be avoided. See also **Foodborne Diseases**.

Sporotrichosis. This disease is a fungal infection caused by a fungus called *Sporothrix schenckii*. It usually infects the skin.

Persons handling thorny plants, sphagnum moss, or baled hay are at increased risk of getting sporotrichosis. Outbreaks have occurred among nursery workers handling sphagnum moss, rose gardeners, children playing on baled hay, and greenhouse workers handling bayberry thorns contaminated by the fungus. A number of cases have recently occurred among nursery workers, especially workers handling sphagnum moss topiaries.

The first symptom is usually a small painless bump resembling an insect bite. It can be red, pink, or purple in color. The bump (nodule) usually appears on the finger, hand, or arm where the fungus first enters through a break on the skin. This is followed by one or more additional bumps or nodules, which open and may resemble boils. Eventually lesions look like open sores (ulcerations) and are very slow to heal. The infection can spread to other areas of the body.

The majority of infections are limited to the skin. Cases of joint, lung, and central nervous system infection have occurred but are very rare. Usually they occur only in persons with previous disorders of the immune system.

Sporotrichosis is generally treated with potassium iodide, taken by mouth in droplet form. A new drug, called itraconazole (Sporanox), is available for treatment, but experience with this drug is still limited. Treatment is often extended over a number of weeks, until the skin lesions are completely healed. See also **Sporotrichosis**.

Strep Throat. See **Group A Streptococcal disease**.

Streptococcus pneumoniae. This disease is the leading cause of bacterial pneumonia, meningitis, and otitis media in the United States.

Each year, *S. pneumoniae* infections cause 100,000–135,000 hospitalizations for pneumonia, 6 million cases of otitis media, and over 60,000 cases of invasive disease, including 3300 cases of meningitis. Incidence of sterile-site infections shows geographic variation from 21 to 33 cases per 100,000 population.

Persons at higher risk for infection are the elderly, children under 2 years old, blacks, American Indians and Alaska Natives, children who attend group day care centers, and persons with underlying medical conditions including HIV infection and sickle-cell disease. See also **Meningitis**.

Toxic Shock Syndrome. A syndrome caused by *Staphylococcus aureus*, a bacterium. Toxic shock syndrome (TSS) manifests by sudden onset of fever 39 to 40.5 °C (102 to 105 °F) which remains elevated, headache, sore throat, chills, vomiting, profuse watery diarrhea, muscle pains and rash. Hypotension and mucous membrane, multisystem involvement and later desquamation are features of the disease.

The *Staphylococcus aureus* commonly colonizes skin and mucous membranes in humans. TSS has been associated with use of tampons and intravaginal contraceptive devices in women and occurs as a complication of skin abscesses or surgery. Those at risk include menstruating women, women using barrier contraceptive devices, and persons who have undergone nasal surgery.

Patients suspected of having TSS, should be hospitalized immediately and treated intensively: tampons, diaphragms, and other foreign bodies should be removed at once. Fluid and electrolyte replacement must be given to prevent or treat hypovolemia, hypotension or shock.

Trachoma. A chronic follicular conjunctivitis, that leads to scarring in the conjunctiva and cornea. Repeat active infections occur in children <10 years of age. Subsequently, conjunctival scarring (cicatricial disease) and inversion of the eyelashes so they irritate the cornea (trichiasis) develops as a result of earlier infections. Trichiasis predisposes to corneal ulceration and corneal opacities resulting in decreased vision and blindness. See also **Trachoma**.

Typhoid fever. A life-threatening illness caused by the bacterium *Salmonella* Typhi. In the United States about 400 cases occur each year, and 70% of these are acquired while traveling internationally. Typhoid fever is still common in the developing world, where it affects about 12.5 million persons each year.

Typhoid fever can be prevented and can usually be treated with antibiotics. If you are planning to travel outside the United States, you should know about typhoid fever and what steps you can take to protect yourself.

Salmonella Typhi lives only in humans. Persons with typhoid fever carry the bacteria in their bloodstream and intestinal tract. In addition, a small number of persons, called carriers, recover from typhoid fever but continue to carry the bacteria. Both ill persons and carriers shed *S. Typhi* in their feces (stool).

Persons with typhoid fever usually have a sustained fever as high as 103° to 104 °F (39° to 40 °C). They may also feel weak, or have stomach pains, headache, or loss of appetite. In some cases, patients have a rash of flat, rose-colored spots. The only way to know for sure if an illness is typhoid fever is to have samples of stool or blood tested for the presence of *S. Typhi*.

You can get typhoid fever if you eat food or drink beverages that have been handled by a person who is shedding *S. Typhi* or if sewage contaminated with *S. Typhi* bacteria gets into the water you use for drinking or washing food. Therefore, typhoid fever is more common in areas of the world where handwashing is less frequent and water is likely to be contaminated with sewage.

Once *S. Typhi* bacteria are eaten or drunk, they multiply and spread into the bloodstream. The body reacts with fever and other signs and symptoms.

Typhoid fever is common in most parts of the world except in industrialized regions such as the United States, Canada, western Europe, Australia, and Japan. Therefore, if you are traveling to the developing world, you should consider taking precautions. Over the past 10 years, travelers from the United States to Asia, Africa, and Latin America have been especially at risk.

If you are traveling to a country where typhoid is common, you should consider being vaccinated against typhoid. Visit a doctor or travel clinic to discuss your vaccination options.

Remember that you will need to complete your vaccination at least 1 week before you travel so that the vaccine has time to take effect. Typhoid vaccines lose effectiveness after several years; if you were vaccinated in the past, check with your doctor to see if it is time for a booster vaccination. Taking antibiotics will not prevent typhoid fever; they only help treat it. See also **Typhoid Fever**.

Ulcer Disease. See **Helicobacter pylori**.

Urinary Tract Infections. Symptoms range from painful urination in uncomplicated urethritis or cystitis to severe systemic illness associated with abdominal or back pain, fever, sepsis and decreased kidney function in some cases of pyelonephritis.

Urinary tract infections are usually caused by *Escherichia coli*, but other Enterobacteriaceae are also important causes of infection.

In the United States, urinary track infections (UTIs) account for about 4 million ambulatory-care visits each year, representing about 1% of all outpatient visits. See also **Kidney and Urinary Tract**.

Vibrio parahaemolyticus. *Vibrio parahaemolyticus* is bacterium in the same family as those that cause cholera. It lives in brackish saltwater and causes gastrointestinal illness in humans. *V. parahaemolyticus* naturally inhabits coastal waters in the United States and Canada and is present in higher concentrations during summer; it is a halophilic, or salt-requiring organism.

When ingested, *V. parahaemolyticus* causes watery diarrhea often with abdominal cramping, nausea, vomiting fever and chills. Usually these symptoms occur within 24 hours of ingestion. Illness is usually self-limited and lasts 3 days. Severe disease is rare and occurs more commonly in persons with weakened immune systems. *V. parahaemolyticus* can also cause an infection of the skin when an open wound is exposed to warm seawater.

Most people become infected by eating raw or undercooked shellfish, particularly oysters. Less commonly, this organism can cause an infection in the skin when an open wound is exposed to warm seawater.

In Asia, *V. parahaemolyticus* is a common cause of foodborne disease. In the United States, it is less commonly recognized as a cause of illness, partly because clinical laboratories rarely use the selective medium that is necessary to identify this organism. Not all states require that *V. parahemolyticus* infections be reported to the state health department, but CDC collaborates with the Gulf Coast states of Alabama,

Florida, Louisiana, and Texas to monitor the number of cases of Vibrio infection in this region. From those states, about 30–40 cases of *V. parahaemolyticus* infections are reported each year. The Foodborne Diseases Active Surveillance Network, Food Net, also tracks *V. parahaemolyticus* in regions outside the Gulf Coast. In 1997, the incidence of diagnosed *V. parahaemolyticus* infection in Food Net sites was. 25/100,000. See also **Foodborne Diseases**.

Vibrio vulnificus. *Vibrio vulnificus* is a bacterium in the same family as those that cause cholera. It normally lives in warm seawater and is part of a group of vibrios that are called "halophilic" because they require salt.

V. vulnificus can cause disease in those who eat contaminated seafood or have an open wound that is exposed to seawater. Among healthy people, ingestion of *V. vulnificus* can cause vomiting, diarrhea, and abdominal pain. In immunocompromised persons, particularly those with chronic liver disease, *V. vulnificus* can infect the bloodstream, causing a severe and life-threatening illness characterized by fever and chills, decreased blood pressure (septic shock), and blistering skin lesions. *V. vulnificus* bloodstream infections are fatal about 50% of the time.

V. vulnificus can also cause an infection of the skin when open wounds are exposed to warm seawater; these infections may lead to skin breakdown and ulceration. Persons who are immunocompromised are at higher risk for invasion of the organism into the bloodstream and potentially fatal complications.

Yersinia enterocolitica. Yersiniosis is an infectious disease caused by a bacterium of the genus *Yersinia*. In the United States, most human illness is caused by one species, *Y. enterocolitica*. Infection with *Y. enterocolitica* can cause a variety of symptoms depending on the age of the person infected. Infection with *Y. enterocolitica* occurs most often in young children. Common symptoms in children are fever, abdominal pain, and diarrhea, which is often bloody. Symptoms typically develop 4 to 7 days after exposure and may last 1 to 3 weeks or longer. In older children and adults, right-sided abdominal pain and fever may be the predominant symptoms, and may be confused with appendicitis. In a small proportion of cases, complications such as skin rash, joint pains, or spread of bacteria to the bloodstream can occur.

Y. enterocolitica belongs to a family of rod-shaped bacteria. Other species of bacteria in this family include *Y. pseudotuberculosis*, which causes an illness similar to *Y. enterocolitica*, and *Y. pestis*, which causes plague. Only a few strains of *Y. enterocolitica* cause illness in humans. The major animal reservoir for *Y. enterocolitica* strains that cause human illness is pigs, but other strains are also found in many other animals including rodents, rabbits, sheep, cattle, horses, dogs, and cats. In pigs, the bacteria are most likely to be found on the tonsils.

Infection is most often acquired by eating contaminated food, especially raw or undercooked pork products. The preparation of raw pork intestines (chitterlings) may be particularly risky. Infants can be infected if their caretakers handle raw chitterlings and then do not adequately clean their hands before handling the infant or the infant's toys, bottles, or pacifiers. Drinking contaminated unpasteurized milk or untreated water can also transmit the infection. Occasionally *Y. enterocolitica* infection occurs after contact with infected animals. On rare occasions, it can be transmitted as a result of the bacterium passing from the stools or soiled fingers of one person to the mouth of another person. This may happen when basic hygiene and handwashing habits are inadequate. Rarely, the organism is transmitted through contaminated blood during a transfusion.

Y. enterocolitica infections are generally diagnosed by detecting th organism in the stools. Many laboratories do not routinely test for *Y. enterocolitica*, so it is important to notify laboratory personnel when infection with this bacterium is suspected so that, special tests can be done. The organism can also be recovered from other sites, including the throat, lymph nodes, joint fluid, urine, bile, and blood.

Uncomplicated cases of diarrhea due to *Y. enterocolitica* usually resolve on their own without antibiotic treatment. However, in more severe or complicated infections, antibiotics such as aminoglycosides, doxycycline, trimethoprim-sulfamethoxazole, or fluoroquinolones may be useful.

Most infections are uncomplicated and resolve completely. Occasionally, some persons develop joint pain, most commonly in the knees, ankles or wrists. These joint pains usually develop about 1 month after the initial episode of diarrhea and generally resolve after 1 to 6 months. A skin rash, called "erythema nodosum," may also appear on the legs and trunk; this is more common in women. In most cases, erythema nodosum resolves spontaneously within a month.

Center for Disease Control and Prevention (CDC), Atlanta, GA

BACTERIOLOGY. Bacteriology is the study of bacteria, a large and diverse group of microscopic organisms that exist as single cells or cell clusters. Bacteria are a major class of microorganisms, which also include protists (microbial eukaryotes) and viruses, the latter of which are microscopic but not cellular. Bacteria are first and foremost cells, and as such, show all the properties of living systems. These include metabolism, reproduction (growth), differentiation, communication, movement and evolution.

Examination of the internal structure of cells reveals two patterns; prokaryotic and eukaryotic (Figure 1). Eukaryotic cells are typically larger and structurally more complex than prokaryotic cells. Microbial eukaryotic cells include the algae, fungi and protozoa. In contrast to eukaryotic cells, bacteria are prokaryotic cells and have a simpler internal structure, lacking membrane-enclosed organelles such as a nucleus, mitochondria and chloroplasts (Figure 1).

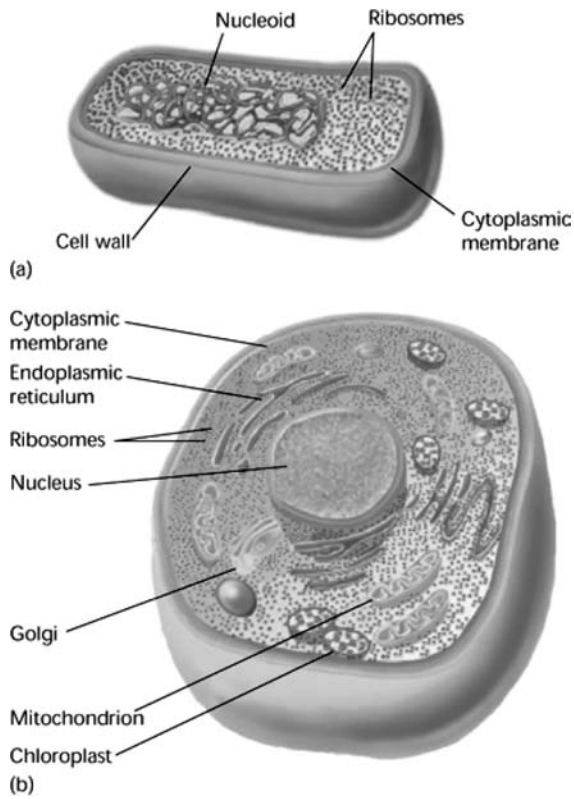

Fig. 1. Cell structure of (**a**) prokaryotic and (**b**) eukaryotic cells. Note the presence of membrane-enclosed organelles (nucleus, mitochondria and chloroplasts) in the eukaryotic cells, as well as the presence of various other membranous structures. For a depiction of the origin of the mitochondrion and the chloroplast, see Figure 3.

With rare exception, the deoxyribonucleic acid (DNA) of prokaryotic cells is arranged in a single circular molecule called the nucleoid. This structure is twisted and contorted in such a way as to fit inside the very limited cell volume available in a prokaryotic cell. A typical rod-shaped prokaryote such as the intestinal bacterium *Escherichia coli* has dimensions of 1×2 μm and a cell volume of about 2 μm^3. Despite this small size, all cellular components necessary for life, including a cell wall, cytoplasmic membrane, ribosome's, cytoplasm and nucleoid (which in *E. coli*, contains 4.68 million base pairs of DNA) (Figure 1) are contained within the cell structure.

Since microbial cells have left relatively few visible clues to their phylogenetic (evolutionary) backgrounds, analyses of their genes are necessary to derive phylogenetic (evolutionary) relationships. The most insightful of these analyses has been the comparative sequencing of ribosomal ribonucleic acid (rRNA), a major class of RNA that plays both structural and catalytic roles in ribosomes, the cell's protein synthesis factories. Methods for sequencing and analyzing genes encoding rRNA are now routine. From sequence analyses, computer algorithms can construct trees that depict the phylogenetic history of the selected organisms.

The results of comparative ribosomal RNA gene sequencing show that three phylogenetic domains of cells exist. Two domains of prokaryotes are known: the *Bacteria* and the *Archaea*. The third domain of life, the *Eukarya*, includes all eukaryotic cells. (Since these domain names are formally considered the highest rank among biological taxons, the terms *Bacteria, Archaea, and Eukarya* are set in italics.) The domains are thought to have diverged from a common ancestral organism early in the history of life (Figure 2). Surprisingly, the rRNA tree of life shows that *Archaea* are phylogenetically more closely related to eukaryotes than to *Bacteria*, despite the fact that *Archaea* and *Bacteria* are prokaryotes and *Eukarya* are eukaryotes. The phylogenetic tree of life has been strongly supported by comparative sequence analyses of several other genes and proteins as well. See also **Cell (Biology)**.

The rRNA picture of evolution has confirmed the long-held hypothesis that all life forms are related at some level. However, at the same time it has revealed that not all prokaryotic cells are necessarily closely related. Comparative rRNA gene sequencing filled an important void in biology: it spawned the first experimentally derived evolutionary framework for the prokaryotes. Such information had been lacking in microbiology since its inception. But in addition, rRNA-based phylogenetic methods triggered the development of new research(tools that have impacted many subdisciplines of microbiology, including microbial systematics, microbial ecology and clinical and diagnostic microbiology.

These new molecular tools complement (or even replace in some cases) many of the classical methods for characterizing and identifying prokaryotes. Moreover, these methods are not limited to use with pure cultures but can be used to identify prokaryotes in natural samples, such as soil and water, or in clinical specimens. The conclusions of these types of studies have been sobering. Using comparative rRNA gene sequencing methods and other now routine molecular biological methods, total DNA can be extracted from a microbial habitat and the microorganisms inventoried. For example, all of the rRNA genes from organisms in a soil sample can be isolated, sorted out, and sequenced, and the results plotted on a phylogenetic tree. Such trees invariably show an enormous diversity of organisms in virtually any habitat, most of which have not yet been observed in laboratory cultures. Indeed, microbiologists now suspect that less than 1% of the species of *Bacteria* and *Archaea* have been grown in the laboratory.

Taxonomy is the science of classification and consists of two major components, identification and nomenclature. The accurate identification of a prokaryote is important for several reasons. For example, because drug susceptibilities differ among different bacteria, in clinical microbiology the accurate identification of a pathogenic (disease-causing) bacterium greatly assists in treatment of the disease. In bacterial systematics accurate identification is important to differentiate organisms, recognize new species, and to build criteria for defining bacterial species. As the species concept currently exists in bacteriology, individual species are defined on a combination of their phenotypic properties (primarily morphology and metabolism) and phylogeny (rRNA sequence). Although we have not yet arrived at the point where complete genome sequences are used as the basis of speculating prokaryotes, the rapid advancement in nucleic acid sequencing technology points to a genome-based systematics of prokaryotes in the not-too-distant future.

A major repository of taxonomic and phylogenetic data on prokaryotes is *Bergey's Manual of Systematic Bacteriology*. This multivolume treatise is a collection of phenotypic and rRNA sequencing data on all recognized species of prokaryotes, primarily those available in laboratory culture. Each chapter of *Bergey's Manual* is written by an expert and contains tables, photos, diagrams and other data useful for identification purposes. Although *Bergey's Manual* makes no claim to be the "official" taxonomy of the prokaryotes, it is widely considered to be the most comprehensive treatment of the subject. *Bergey's Manual* has existed for over 80 years (the first eight editions were titled *Bergey's Manual of Determinative Bacteriology*), but only in the most recent volume has the full impact of the rRNA sequencing revolution been felt.

The Chimaeric Nature of the Eukaryotic Cell

In contrast to prokaryotic cells, eukaryotic cells are typically much larger and contain membrane-bound organelles. These include first and foremost the nucleus, home for the cell's genome, and the site of major molecular processes including DNA replication and RNA synthesis (transcription). The other major organelles include the mitochondrion and chloroplast (Figure 1). Aeons ago, mitochondria and chloroplasts were free-living prokaryotic cells. We know this because today, as organelles, these stripped down prokaryotic cells retain many aspects of their previous lifestyle including the presence of a circular DNA genome and ribosome's.

From molecular sequencing of their rRNA, the prokaryotic history of organelles is clear. Organelles originated from the stable incorporation of cells of particular lineages of *Bacteria* into organelle-free cells of *Eukarya*. This process is called *endosymbiosis*, the word "endo" meaning

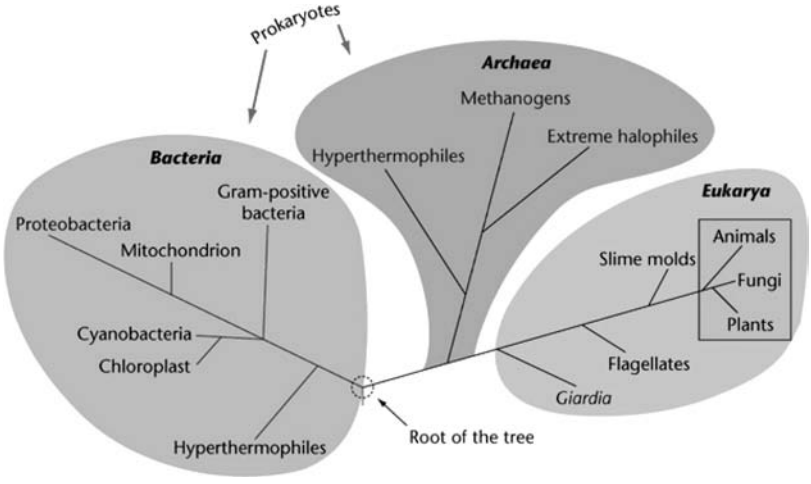

Fig. 2. The phylogenetic tree of life. This tree depicts the evolutionary relationships of cells based on comparative ribosomal RNA sequencing. The tree clearly reveals the three domains of life, the *Bacteria*, the *Archaea* and the *Eukarya*.

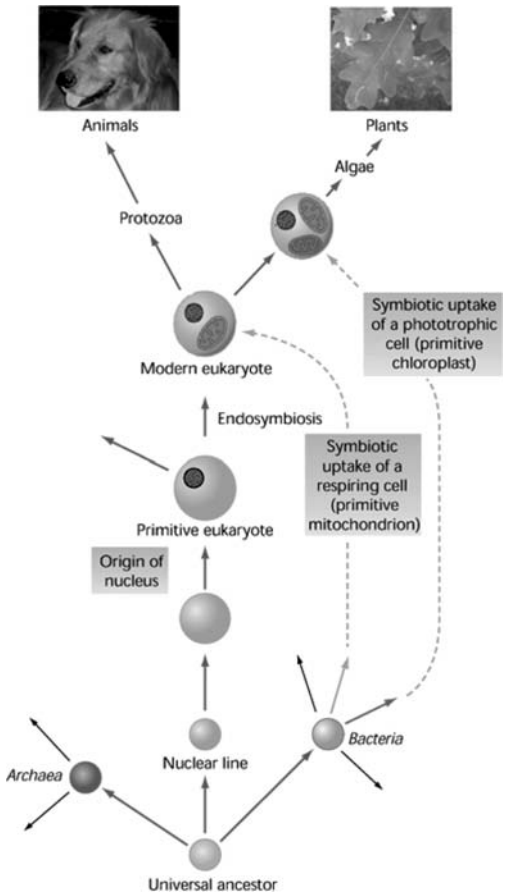

Fig. 3. Endosymbiosis. It is hypothesized that the modern organelle-containing eukaryotic cell evolved from ancestral eukaryotic cells that lacked organelles. Note that the mitochondrion and the chloroplast of modern eukaryotic cells emerged from lineages within the domain *Bacteria*.

"inside" and the word "symbiosis" meaning "a relationship beneficial to both parties" (Figure 3). Organelles provide the eukaryotic cell with energy from respiration (the mitochondrion) or photosynthesis (the chloroplast) in exchange for a stable and protected residency. Since the mitochondrion and the chloroplast have phylogenetic roots in distinct lineages of *Bacteria*, the eukaryotic cell is a genetic chimaera. That is, nonphototrophic eukaryotic cells contain genes from two different sources (nuclear and mitochondrial) while phototrophic eukaryotes contain genes from three different sources (nuclear, mitochondrial and chloroplast) (Figure 3).

Morphological and Physiological Diversity of Prokaryotes

Prokaryotes come in many different shapes (morphologies) and sizes. A common morphology for prokaryotes is the rod, a simple form in which the cell is longer in one dimension than in the other. Rods can be short, long, thin or fat, depending on the organism. Other common morphologies include the coccus (cocci) where cells are spherical or nearly so, the spirillum (spirilla), where a rod-shaped cell is curved along its long axis to form a spiral shape, the spirochaete, a highly twisted thin rod that forms a coil, and the filament, essentially a very long rod. Many variations of these morphologies are known, including cells that form protrusions called buds, and some that are even square. However, the most common morphologies for prokaryotes are the rod and the coccus.

Energy to drive life processes can be obtained from three sources: organic chemicals, inorganic chemicals or light. Most prokaryotes conserve energy released during the oxidation of organic compounds. Such organisms are called *chemoorganotrophs*. Many prokaryotes can tap the energy available from the oxidation of inorganic substances, such as H_2, Fe^{2+}, H_2S, and NH_4^+; these are the chemolithotrophs. Finally, phototrophic prokaryotes carry out photosynthesis and are able to obtain all of their energy needs from sunlight.

Prokaryotes are physiologically highly diverse and their metabolic diversity far exceeds that of eukaryotes. Collectively, prokaryotes have exploited every conceivable means of "making a living" consistent with the laws of chemistry and physics. Thousands of different organic chemicals can be metabolized by one prokaryote or another and these organisms are masters at inhabiting unusual environments. For example, many prokaryotes can thrive in the complete absence of oxygen (anoxia), a condition that supports the growth of only a handful of eukaryotic cells. In fact, some anaerobic prokaryotes are so sensitive to oxygen that they are killed by even a brief exposure to it. Because many places on Earth are anoxic or nearly so, there exist many habitats in which anaerobic prokaryotes dominate.

Some microbial habitats are so harsh that they support only the hardiest of prokaryotes. Extreme environments, defined by one or more environmental extreme such as high or low temperature, pH or salinity, are often bustling with prokaryotic life. Boiling hot springs, for example, support a diverse population of hyperthermophiles, prokaryotes that thrive in very hot water. Hyperthermophiles are known that even grow above the boiling point of water (100 °C (212 °F), the current record holder being capable of growth to 121 °C (250 °F). Highly acidic or highly alkaline environments, or very salty environments, are teeming with acidophilic, alkaliphilic and halophilic prokaryotes, respectively. Constantly cold temperatures, such as prevails in the Arctic and Antarctic, as well as in marine sediments, are suitable for the development of cold-loving (psychrophilic) prokaryotes. Other than environments that are very hot, these extreme environments contain some microbial eukaryotes as well.

Collectively, microorganisms that thrive under various extreme conditions are known as extremophiles, and the current record holders in each category are all prokaryotic cells. Interestingly, these organisms are not just "tolerant" of these environmental extremes, but "actually require them" in order to grow. Thus, the hyperthermophilic prokaryote *Pyrolobus*, a member of the domain *Archaea*, fails to grow at 90 °C (194 °F), not because it is too hot, but because it is not hot enough! The growth temperature optimum of *Pyrolobus* is 106 °C (223 °F). The physiological diversity of prokaryotes, coupled with their ability to inhabit virtually any environment on Earth, is responsible for the major impacts these organisms have on the make-up and functioning of the biosphere. Indeed, all life forms on earth depend in one way or another on the activities of prokaryotes.

Trends in Microbiology: From Medical to General Molecular Microbiology

Although bacteria were first observed microscopically over 325 years ago, microbiology as a science did not blossom until the end of the nineteenth century. Since that time, the field has exploded and spawned several new but related fields. For microbiology to develop, improvements in microscopy were necessary in order to visualize cells as small as bacteria. But in addition, some basic methods were needed in order to handle culture and study bacteria effectively.

The suspicion that bacteria could cause disease was the spark for the development of techniques to study them. The greatest contributions in this regard came from the German physician Robert Koch (1843–1910) and the many associates that studied under him. In Koch's triumphal studies of the diseases anthrax, tuberculosis and cholera, he established a set of objective criteria that came to be known as "Koch's postulates" for proving that a particular microorganism caused a particular disease. Koch's work and his postulates emphasized the laboratory culture of suspected pathogens, and many of the simple methods first developed in Koch's laboratory remain key techniques in microbiology today. See also **Koch, Heinrich Hermann Robert (1843–1910)**.

In the twentieth century the field of bacteriology developed rapidly in two major directions, basic (fundamental discovery), and applied (solving microbiological problems). In the years following the great Koch discoveries, many subdisciplines of bacteriology emerged, including soil, industrial, marine and aquatic bacteriology. Research in these fields sought to reveal the diversity of prokaryotes in specific habitats (basic science) or to identify the beneficial or detrimental activities they carried out, with the goal of enhancing or inhibiting them, respectively (applied science). The term "general microbiology" was used to encompass all of these areas and was attached to virtually any bacteriological study that was not medically oriented. From this early understanding of the scope and activities of the prokaryotic world, the era of "molecular microbiology" was born. This era is still going strong today, and spawned the most recent bacteriological subdisciplines of biotechnology and genomics.

Worldwide, many microbial challenges still exist in the area of infectious disease. Basic research in bacteriology has led to the discovery of many antibacterial agents effective against the causative agents of a host of

bacterial diseases. But continued basic research is critically important to maintaining an arsenal of effective antibacterial weapons. This is because today the major challenge in medical bacteriology is not so much the treatment of infectious diseases caused by newly discovered bacterial pathogens, but instead is the problem of drug resistance in well-known pathogens previously held in check by classical antibiotics, such as penicillin and tetracycline.

Influence of Bacteriology on Genetics and Molecular Biology

The important subdisciplines of molecular genetics and molecular biology also emerged from the field of bacteriology. Bacteria share many biochemical properties with cells of higher organisms. Moreover, bacteria can be grown to extremely high densities in laboratory culture and are readily amenable to biochemical and genetic study. All of these features make bacteria excellent models for understanding cell function in higher organisms, including humans.

The discovery that DNA was the cell's genetic material emerged from classical studies of the mechanism of transformation, a genetic process in prokaryotes in which DNA from one organism is taken up and incorporated into the DNA of a second. When the incorporated DNA was shown to alter the genetic properties of the second organism, proof was obtained that genes — the units of inheritance — consisted of DNA. These experiments on bacterial transformation opened the era of nucleic acid biology and showed that proteins, although vital to the functions of a cell, did not themselves carry genetic information, an idea widely held at the time.

The focus on DNA as the genetic material brought about by these studies led to the determination of the structure of this molecule — the now famous "double helix" — and to an understanding of the molecular mechanisms of inheritance and mutation. The later discoveries of other genetic transfer processes in bacteria including conjugation (a form of "mating" requiring cell-to-cell contact) and transduction (a form of genetic transfer in which a bacterial virus shuttles genes from one cell to another), triggered the era of molecular microbiology, the era that is bearing abundant fruit today.

Today molecular biology has taken us into the world of genomics. The word genomics refers to the discipline of mapping, sequencing, analyzing and comparing the genome (a cell's entire complement of genes) of different cells. Genome sequencing projects began with the tiny genomes of viruses. Then, as sequencing technology improved, the complete sequence of various bacterial genomes began to appear; the results of the first such breakthrough were published in 1995. Today, hundreds of genome sequences have been determined, including several hundred prokaryotic genomes and many eukaryotic microbial genomes. Moreover, the genomes of several higher organisms are also complete, including, of course, the human genome. See **Human Genome Project (The)**.

Although still a major undertaking, bacterial genome sequencing projects are approaching the point of being routine operations, and thus the genetic blueprints of more and more prokaryotes are entered into the databases yearly. Table 1 lists information on a few bacterial genomes, including some of the largest and some of the smallest genomes sequenced to date. We can conclude from Table 1 that the genomes of prokaryotes vary in size over more than a 20-fold range and that the smallest genomes contain about one half million DNA base pairs. It has also been observed that in prokaryotes, the number of genes encoded by an organism's genome is proportional to genome size, with an average gene consisting of about 1000 nucleotide base pairs (Table 1). Such a relationship does not hold for eukaryotic cells, where introns (noncoding DNA sequences) are interspersed with coding sequences (exons) in most genes in the genome. In fact, intron DNA can make up a major fraction of the genome. For example, only about one percent of the human genome encodes protein, the remainder being noncoding DNA. Although some DNA in prokaryotes is noncoding DNA, introns, per se, are very rare in prokaryotes.

For many proteins, the genes that encode them can easily be recognized from their DNA sequences. Because of this, it is possible to compare two genome sequences to reveal their similarities and differences and determine the proteins their genes encode. From such studies, several conclusions can be drawn. First, many genes in species of *Archaea* have very close relatives in species of *Eukarya*, a finding predictable from the phylogenetic relationships between these two domains of cells (Figure 2). However, many genes in *Archaea* also share sequence similarity with genes from *Bacteria*. This could be a result of their (albeit more distant) phylogenetic connections (Figure 2) and/or be due to gene exchange between cells in the two domains. Indeed, the forms of genetic transfer discussed earlier and first discovered in *Bacteria* also occur in *Archaea*. Thus, interdomain gene exchange should be expected.

Comparative genomics has shown us that different prokaryotes contain different complements of genes. It is therefore possible to use genomics to predict the ecology, behavior, or pathogenic/beneficial potential of a given prokaryote. However, besides just comparing genetic blueprints, several generalizations have emerged from comparative genomic studies. For example, the smaller an organism's genome, the greater the percentage of its genes turn out to be devoted to core cellular processes, such as DNA replication and protein synthesis (translation). As genomes enlarge (transcription), they tend to contain more regulatory genes — genes that control the expression of other genes –and "sensory" genes, genes that encode proteins that allow cells to sense chemical or physical signals in their habitats. Moreover, only about 70% of the genes in any given genome can be identified as encoding known proteins. Roughly 30% of the genes in any given genome are therefore unique, encoding proteins of unknown function. This indicates that a huge reservoir of untapped genes exists among prokaryotes, good news indeed for the pharmaceutical and biotechnology industries that specialize in developing new microbial products.

Prokaryotes in Science: Medicine, Biotechnology and Evolutionary Research

Prokaryotes have played key roles in medicine, biotechnology and evolution. For example, despite the fact that most infectious diseases are under control in developed countries, bacterial diseases are still important causes of death in undeveloped countries. The field of biotechnology, born from basic studies with bacteria, employs genetically modified organisms to synthesize products of high commercial value. As will be discussed in the following section, biotechnology has generated a wealth of valuable human proteins and other therapeutic products for use against infectious, chronic and lifestyle diseases.

Development of the field of molecular evolution can be considered a major triumph for all of biology. Molecular phylogenetic techniques employing comparative rRNA sequencing, although pioneered with the prokaryotes, has been embraced by all of biology as the most powerful tool from which to discern evolutionary relationships. In fact, in combination

TABLE 1. SOME PROKARYOTIC GENOMES

Organism	Domain	Size (base pairs)pairs	Genes	Comments
Nanoarchaeum equitans	*Archaea*	490 885	552	Smallest known cellular genome
Mycoplasma genitalium	*Bacteria*	580 070	470	Smallest genome among *Bacteria*; human pathogen
Chlamydia trachomatis	*Bacteria*	1 042 519	894	Intracellular parasite of humans
Aquifex aeolicus	*Bacteria*	1 551 335	1544	Hyperthermophile, autotroph
Methanothermobacter thermoautotrophicus	*Archaea*	1 751 377	1855	Methanogen, thermophile
Halobacterium salinarium	*Archaea*	2 571 010	2630	Extreme halophile
Sulfolobus solfataricus	*Archaea*	2 992 245	2977	Hyperthermophile, acidophile
Bacillus subtilis	*Bacteria*	4 214 810	4100	Produces endospores
Pseudomonas aeruginosa	*Bacteria*	6 264 403	5570	Metabolically versatile; can be a pathogen
Bradyrhizobium japonicum	*Bacteria*	9 105 828	8317	Nitrogen-fixing bacterium; forms root nodules on soybean plants
Escherichia Coli	*Bacteria*	4 639 221	4288	Model organism for molecular biology

with full genomic analyses, molecular phylogeny has revolutionized biology in a way not seen since the discovery of DNA. As we have seen, the goal of constructing a universal phylogenetic tree (Figure 2) has now been accomplished. The challenge for the future is to flesh out the details of this tree and understand the role that genetic exchange has played in shaping the genomes of prokaryotes.

Authentic and Genetically Engineered Prokaryotes in Basic and Applied Science

Bacteria can be harnessed to make many useful products, and industrial microbiology and biotechnology have been the venues for these products. Industrial microbiology employs bacteria to synthesize products on a large scale. The processes used are enhancements of metabolic reactions that the bacteria are already capable of, with the goal being to simply overproduce the product of interest. In biotechnology, by contrast, genetic engineering is used to genetically modify bacteria to synthesize a product not naturally made by the organism, typically on a much smaller scale than in industrial microbiology. Industrial microbiology and biotechnology are thus complementary disciplines. The former is focused on relatively low-value commodities while the latter is focused on highly valuable metabolites.

Examples of products in industrial microbiology include first and foremost, the antibiotics. With the exception of penicillin and structurally related drugs, most clinically useful antibiotics are produced by species of *Bacteria*, in particular, species of *Streptomyces*. These include such major drugs as tetracycline, streptomycin, erythromycin, neomycin, bacitracin, vancomycin and their derivatives. Other common products of industrial microbiology include chemicals such as vitamins and amino acids, enzymes for applications in the food, paper and pharmaceutical industries and alcohol (ethanol) for the fuel, beverage and chemical industries. In all of these cases, the substance needs to be produced in large amounts to be cost-effective. See also **Antibiotics**.

The genetic engineering revolution opened up the field of biotechnology, which today is a major industry primarily controlled by the large pharmaceutical houses. A number of therapeutic products are made by genetic engineering, chief among them human proteins used in clinical medicine. Some examples include (1) blood proteins, such as tissue plasminogen activator (TPA), used to dissolve clots; (2) human hormones, including insulin for the treatment of diabetes and epidermal growth factor for promoting wound healing; (3) immune system modulators, such as the antiviral protein interferon and the antitumor agent tumor necrosis factor; and (4) therapeutic enzymes, such as human DNaseI, used in the treatment of cystic fibrosis.

In addition to pure proteins, genetic engineering has made large strides in the areas of vaccine development and transgenic plants and animals. For ethical and safety reasons, fewer studies have focused on human gene therapy, an area of great potential but as of the present, few actual successes. Biotechnological applications in plants have led the way in the transgenic area, with major commercial successes obtained in the areas of herbicide and disease resistance in crop plants. Genetically modified (GM) plant products have now been on the market in the United States for several years, although worldwide use of GM plants has been less extensive. However, the future looks bright for the use of genetically modified crops, especially if we are to meet the food requirements of an ever-growing human population. See also **Genetic Engineering**.

The Importance of Prokaryotes for Maintaining a Sustainable Biosphere

Prokaryotes existed on Earth for billions of years before plants and animals appeared. In fact, the physiological activities of prokaryotes prepared the planet for higher life forms. For example, the cyanobacteria are O_2-evolving phototrophic organisms, similar in this respect to green plants. Cyanobacteria first evolved on an anoxic planet Earth and it was their photosynthetic metabolism that originally oxygenated Earth. Plants and animals today simply recycle this oxygen by photosynthesis and respiration, respectively.

Prokaryotes contribute to the sustainability of Earth's biosphere in countless other ways as well. For example, the bulk of the organic carbon consumed on Earth is a result of microbial activities. But as humans introduce more and more exotic organic compounds into the environment (pesticides, herbicides, plastics, etc.), the physiological capacities of bacteria become increasingly challenged. In agriculture, prokaryotes play key roles in cycling important inorganic nutrients, such as nitrogen and sulfur, generating forms of these elements that are readily incorporated by plants. Prokaryotes also contribute in major ways to the production of energy, methane and ethanol in particular, and to cleaning up pollution created by human activities, a process called bioremediation.

The overwhelming influence of prokaryotes on humans is enormous. From providing the very means of our life support (O_2) to providing us food and energy and cleaning up our messes, prokaryotes are the "silent majority" in the web of life that makes human activities possible. Bacteriology, the study of prokaryotic life forms, has revealed the many roles that prokaryotes play on Earth and has given us the tools to harness the benefits and control the harmful effects of these organisms. Continued study of the prokaryotes will undoubtedly reveal countless other ways in which these organisms control the workings of the biosphere. For now, we should be very impressed with the power and influence of such small living organisms.

BACTERIOLOGY (The History). The term bacteriology was first used in the early 1880s when it designated the science of the disease-germs, a new specialism in medicine. There had been speculation and research on the relationship between microorganisms and disease for many centuries, but what changed in the 1880s was the invention of laboratory methods and pathological models that allowed investigators to show causal linkages between bacteria and specific diseases. The methods that were at the core of bacteriology — microscopy, culturing and experimental inoculations in laboratory animals — were then developed further by researchers to show how diseases were communicated and how microorganisms produced disease syndromes. The aim that early bacteriologists set themselves was to identify the specific microorganisms responsible for every communicable disease, and then to find ways of destroying these organisms or halting their transmission. See also **Bacteriology**.

Bacteriology was essentially a German creation, developing from the experimental researches of Robert Koch. Between 1876 and 1882, Koch produced convincing evidence of the bacterial cause of anthrax, septic infections and tuberculosis, and in so doing developed innovative techniques in microscopy, staining, solid plate culturing, and vivisection. His germ discoveries and methods had their greatest moment in 1882, when his announcement that tuberculosis was a contagious disease attracted medical and public attention across Europe and North America. An important reason why scientists were interested in his work was that he seemed to have provided the tools and ideas for others to make their own discoveries and achieve fame, if not fortune. German methods and institutional forms were emulated in Britain and the United States, especially as many doctors and scientists traveled to work with Koch and his assistants. In France, the study of bacteria was covered in the putatively wider discipline of microbiology, and the different methods and concerns of Louis Pasteur were dominant. In all countries, the initial boundaries of bacteriology seem to have been more variable than those of other new specialisms, being shaped by the diverse origins of its practitioners and its applied orientation. An additional complication was that the new types of microorganisms being revealed by experimentalists and naturalists challenged existing classificatory schemes in botany and zoology. By the 1880s, most naturalists accepted that bacteria were plants. However, there were scientists who thought they were too primitive to ascribe to either botany or zoology. Also, while medical bacteriology was the dominant form in the 1880s, investigations of bacteria were also being pursued by chemists in the context of water pollution, by brewers in their management of fermentation, and by botanists interested in fungi, soil conditions and plant pathology. See also **Koch, Heinrich Hermann Robert (1843–1910)**; and **Tuberculosis**.

Bacteria are now defined as single-cell, non-nucleated microorganisms that reproduce by binary division, although some species can produce spores and in certain conditions mixing of genetic material may occur. Bacteria are now known to have a variety of feeding mechanisms and most are aerobic, but there are anaerobic species and some species vary their respiration depending on conditions. In the 1880s none of these distinctions or properties was clear-cut and terms like *infusoria*, *germ*, *microbe*, *pathophyte*, *saprophyte* and *Monad* were used, though the preferred term was the *Schizomycetes*, literally the 'splitting-fungi' or 'fission-fungi'. At this time, the boundaries between viruses, bacteria, single-cell nucleated animals, single-cell nucleated plants, and fungi did not have their modern significance. Indeed, the division between bacteria and nonlife was ill defined, not least because until the late 1870s the spontaneous generation of life from inorganic or organic chemicals had seemed possible. The modern sense of a 'virus' as ultramicroscopic, obligate, intracellular parasites was not created until the early twentieth century, and it was not until the 1930s that virology was developed as a distinct specialism apart from bacteriology. For most of the nineteenth century 'virus' meant any agent that could excite a contagious or septic disease, with most doctors assuming that it was a chemical poison, or a complex molecule that had the properties of a living organism. See also **Virology (The History)**.

The Origins of Bacteriology

Medically based histories of bacteriology trace its origins back to ancient ideas on contagion. However, it is more usual to begin with Antoni van Leeuwenhoek (1632–1723), the invention of the microscope, and his revelation of the richness of the fauna and flora of the micro-world. His work provided a great stimulus to the development of microscopy and its use in natural history. However, technical limitations, along with uncertainties about the nature and stability of microorganisms, meant that the replication of observations was difficult. Unsurprisingly, due to the primacy he gave to external sexual characteristics, Linnaeus only offered a perfunctory classification of microorganisms, placing them in the group 'Vermes' (worms) and the class 'Chaos' (formless). The classification system that was the source of all that followed, down to the present day, was developed by the Danish naturalist Otto Friedrich Müller. His scheme for the infusoria, the preferred term in the late eighteenth century, was taken up by C. G. Ehrenberg (1795–1876) in a major new system published in 1838. Ehrenberg's infusoria included microorganisms of all types, arranged in 22 families that he classified by shape, assuming that all organisms were fixed species. Later, simpler classificatory schemes were introduced by Félix Dujardin and Maximilian Petty who also used form as the main criterion. However, the most important developments in classification were made in the 1850s and after by the German botanist Ferdinand Cohn (1828–1898). See also **Cohn, Ferdinand Julius (1828–1898)**; **Dujardin, Félix (1801–1860)**; **Leeuwenhoek, Antoni van (1632–1723)**; and **Linnaeus, Carl (Linné) (1707–1778)**.

In the 1850s, Cohn suggested that 'bacteria' were microscopic plants rather than animalcules, and close to algae and fungi. The same line of argument was also followed by Cohn's great rival Carl Nägeli, who coined the term *Schizomycetes*. However, Nägeli worked with quite different assumptions from Cohn; he regarded the form of schizomycetes as changeable (pleomorphism) and thought these fungi could arise by spontaneous generation. Such views were often linked to the assumption that the physiological actions of fission-fungi were mutable, with both form and function determined by the environment they found themselves in. Both issues — fixed species versus pleomorphism and ancestral versus spontaneous origins — were the subject of debate and investigations in the 1870s, especially in medicine where they were linked to different germ theories of disease. However, it was Cohn's scheme published in 1872, refined in 1875 and 1876, which eventually brought closure to the issues of classification and first defined the domain of bacteriology. In his mature scheme, Cohn placed bacteria into four groups based on shape: Sphaerobacteria (round forms, later cocci); Bacterium (rod-shaped forms); Desmobacteria (thread- or filament-like, later bacilli); and Spirobacteria (motile forms with screw-like tails, later spirilla). It is worth noting that the fact that the word 'bacteria' was used for both the whole group and one specific subgroup caused no problems for contemporary doctors and scientists.

Cohn's work was received in the context of controversies over germ theories of disease in medicine, which had been stimulated in large part by the adoption by a number of doctors of Pasteur's ideas on the nature of fermentation and putrefaction. A chemist by training, Pasteur had been commissioned by French agricultural agencies in the 1850s to investigate diseases that affected the production of wine and then silkworms. During these studies, Pasteur began to champion the idea that fermentation, and by analogy putrefaction, was a biological rather than a chemical process. He claimed that it was due to the action of microorganisms or living germs, rather than molecular catalysts or chemical ferments. Doctors had long drawn parallels between fermentation and the bodily changes observed with fevers and contagious diseases, and between putrefaction and septic infections. Yet, many doctors at this time still found it hard to accept the type of single cause models derived from Pasteur's work and the profession became bitterly divided over the issue. Pasteur was the main opponent of spontaneous generation in the 1860s and although the doctrine lost support amongst biologists in the 1870s, it was Koch's ideas and methods in the early 1880s that finally ended debate on the question in medicine and surgery. See also **Pasteur, Louis (1822–1895)**.

Medical Bacteriology

Koch's standing in science and medicine derived first from his demonstrations that specific microorganisms caused specific disease. With anthrax in 1876, he set new standards by using microscopy to show precisely how the disease was communicated and how the anthrax bacillus behaved to produce the disease syndrome. He repeated the feat with discovery claims for streptococcal infections in 1879, tuberculosis in 1882, and cholera in 1883, the latter two being very high profile developments. However, Koch's pivotal place in the origins of bacteriology came from his innovations in seeing, handling and using bacteria. In microscopy, he utilized new methods that improved magnification, plus old and new dyestuffs to stain specimens differentially. He also used photomicroscopy to illustrate and communicate his findings. For handling bacteria, he developed solid-plate culturing to replace growing them in liquid media in test tubes. When grown on solid media, usually agar gel, bacteria displayed distinctive patterns of growth and colors, and it was possible using a fine needle to take very small specimens to seed other plates and eventually to isolate pure cultures of a single species. It was these pure cultures that Koch used in his vivisection work, inoculating bacteria into animals to replicate human diseases, studying their pathogenesis with microscopy and physiological methods. Either singly or together, these techniques had the potential to aid diagnosis by identifying disease-causing germs in patients. Also, they gave researchers powerful tools to track bacteria within the body and in the environment, opening the possibility of identifying the modes of communication and action of the disease-germs of all infectious diseases. See also **Koch, Heinrich Hermann Robert (1843–1910)**.

It was around the teaching and application of Koch's techniques that bacteriology was first institutionalized. Early bacteriological publications were largely laboratory manuals and bacteriology courses were usually extramural practical classes. The "theories and facts" of bacteria and disease, as opposed to methods and techniques, were introduced across the medical curriculum in preclinical and clinical instruction. In the 1880s, it seemed possible that every doctor would emulate the young Koch and have their own small bacteriological laboratory, say, in an alcove of their consulting room, and that the microscope and culture plate would be as commonly used by doctors as the stethoscope and thermometer. However, this did not happen; by the 1890s bacteriology became the preserve of the specialist. There were many reasons for this turn of events. Generally, clinicians were indifferent to the adoption of bacteriological methods, because of their limited value in everyday diagnosis, prognosis and therapy. Second, bacteria turned out to be more numerous and less tractable than first thought, hence their study required time, money and familiarity with sophisticated techniques. There were also burgeoning research applications, not least in using bacteria to create preventive (vaccines) and curative (antisera) products.

Across Europe, North America and soon the whole world, governments, voluntary agencies, private companies and individuals created bacteriological laboratories. The main model was the Institute of Hygiene, founded at the University of Berlin in 1885, both to honor Koch's achievements and to enable him to develop his work further. The Institute offered classes and diagnostic services to clinicians, and provided facilities for Koch himself and the researchers drawn to work with the 'father' of the new discipline. The hope of its supporters and the promise of bacteriologists was that it would help devise new ways to prevent and treat infectious diseases.

In France, an alternative institutional model was created in 1887, the Institut Pasteur. Also founded to honor another great national scientist,

the immediate impetus for establishing the institute was an attempt to improve the availability of Pasteur's rabies vaccine and to stimulate the development of other vaccines. In modern terms, the Institut Pasteur was an immunological agency making vaccines and antisera. However, much of the day-to-day work of its staff was similar to that in Berlin. In subsequent decades Instituts Pasteur were established across the world and many different types of national or municipal bacteriological laboratories were founded. In the late 1880s and 1890s, bacteriology included work on how the body reacted to bacteria, the subject that institutionalized as immunology in the twentieth century. Indeed, in the years around 1900, it was the ability of bacteriologists to produce preventive and curative products that excited medical and public attention. As early as 1890, Koch had caused a sensation with his flawed tuberculin remedy for tuberculosis, which was a substance derived from the culture plate on which the tubercle bacillus (*Mycobacterium tuberculosis*) had grown. However, what really excited popular interest was what followed. First, researchers at Koch's and Pasteur's institutes developed antitoxin treatment for diphtheria, based on injecting sufferers with antidotes to bacteria toxins collected from immune animals. This procedure held out the hope of similar cures for many other communicable diseases. Second, following Pasteur's work on vaccines in the early 1880s, other researchers began to produce vaccines, using killed or altered bacteria to stimulate antibody production, for important diseases, such as cholera, plagues and typhoid fever. Again, it seemed possible that every communicable disease would in time have a preventive vaccine.

Nonmedical Bacteriology

A determining feature of the history of bacteriology is that it began as a medical specialism and the majority of bacteriologists have always worked in medicine. Yet, it was always a wider enterprise; first in other applied fields especially in agricultural and industrial processes, and then in the twentieth century as a division of botany and later biology. To escape the dominance of medical bacteriology various attempts have been made to restyle the subject as microbiology, a term that had advantages and disadvantages. It promised to widen the subject to include viruses (virology), fungi (mycology), algae (botany) and protozoa (zoology), making it a large enterprise with subspecialties. While this made sense to pure scientists and could be created in university departments, the subject's history, fundraisers and practitioners favored more focused structures. An additional problem for those trying to re-engineer the discipline was that most bacteria are either parasitic or saprophytic. Recognition of such properties was implicit in medical bacteriology to the extent that doctors were always conscious of bacteria–host interactions. However, in the context of modern biological science, it meant adopting ecological perspectives, for example, in the biotic and abiotic relationships of microorganisms, and more importantly, looking at parasitic, symbiotic or commensally relationships.

The expertise of the new medical laboratories was sometimes called upon in areas such as water pollution, plant pathology and biological industries, including brewing and dairy products. However, bacteriological work in most of these fields was developed within existing public and private organizations, and mainly by chemists. The control of river pollution had previously relied on analytical chemists monitoring and managing the quantitative levels of metals, salts and organic matter. However, the identification of pathogenic germs raised questions about the qualitative aspects of water contaminants, especially the presence or absence of specific pathogenic organisms. Bacteriological analyses of water proved very difficult. Sampling was a problem, also determining what levels of bacterial contamination, if any, were safe, especially as the fauna and flora of even standing water changed over time. The main practical issue was how to treat water containing dangerous bacteria, particularly the volumes extracted from reservoirs, rivers and wells for domestic supplies. Water analysts developed physical methods (e.g. filtration and sedimentation) and chemical methods (e.g. chlorination) that killed bacteria, though they also found that oxygenating water reduced contaminants. This was because certain free-living species of aerobic bacteria broke down organic matter, so processes were developed (e.g. the activated sludge process) where such organisms were used, in conjunction with aeration, in sewage treatment processes. See also **Water Pollution**.

Apart from its practical value, this development highlighted a new and at the time surprising feature of bacteria, namely, that there were 'good' as well as 'bad' microorganisms. Such was the dominance of medical bacteriology, with its roots in debates about germ theories of disease, that bacteria had been constructed for professional and popular audiences as necessarily pathogenic or dangerous. Of course, Pasteur's living-germ theory of fermentation had pointed to the value of the yeast fungus, but it was a fungus not a bacterium. The value of such work was evident in 1876 at the Carlsberg Brewery in Copenhagen, where a laboratory was established and soon E. Hansen was developing pure yeast cultures. Similar investigations had continued in France in the wake of Pasteur's work on wine, but these concentrated on spoilage rather than fermentation as such, where tradition and rule of thumb methods continued in an industry dominated by small producers. See also **Yeasts and Molds**.

Dairying was the other area of agriculture where bacteriology was deployed, though this was more an extension of public health work as the main issue was the threat that bovine tuberculosis posed to human health. As with water quality, the late nineteenth century saw concerns about general food safety switch from chemical to bacteriological contamination, which led public health laboratories to employ bacteriologists to test foods, especially shellfish, meat and milk. In this context, we should not overlook the introduction of yoghurt into Western Europe and North America in the 1900s. This dairy product was championed by Elie Metchnikoff, one of the most famous scientists at the Institut Pasteur in Paris and originator of models of cellular immunity. He attributed the healthy quality of yoghurt, evident in the longevity of certain peoples in Turkey and Bulgaria, to the Bulgarian bacillus *Lactobacillus bulgaricus*, the microbe responsible for the fermentation of milk and healthy colonization of the gut. See also **Metchnikoff, Elie (Ilya) (1845–1916)**.

The addition of bacteriology to chemistry was also a feature of agricultural science in the late nineteenth century, when scientists working on soil fertility discovered the role of microorganisms in the nitrogen cycle in soil. Bacteria were to be important in fixing atmospheric nitrogen and making nitrates available to plants, with some species free-living in the soil (e.g. *Azotobacter* and *Clostridium*) and others living symbiotically in plants roots (e.g. *Rhizobium*). However, there were also bacteria that reduced soil fertility, especially in anaerobic, waterlogged soil, when they broke down nitrates (e.g. *Pseudomonas*). Knowledge of these processes enabled scientists to inform farmers better; for example, to plough waterlogged soil to avoid denitrification and to use appropriate nitrogen-fixing plants in crop rotations. While the role of bacteria was important in agriculture, it did not compare to the practical and economical significance of fungi and then viruses. Thus, rather than being developed in a separate specialism, agricultural bacteriology was part of the broader discipline of plant pathology, or was part of mycology, where it was secondary to the study of fungi. Generally, the small size of research institutes and teaching departments in agricultural science and applied botany did not favor new discipline formation. None the less, the fact that bacteria and fungi were plants enabled university botany departments to develop applied research to attract funding and consultancy work.

Bacteriology in the Twentieth Century

Bacteriology matured rapidly as a specialism, especially in terms of its methods and institutions. The subject continued to be defined by its medical context, especially as after 1900 the use of bacteriological diagnoses increased, first in public health and then in hospitals. Specialist laboratories were mainly created to meet the demand for the monitoring of infectious diseases in communities. In the first quarter of the century the main tests carried out in these service laboratories were for typhoid fever, diphtheria, tuberculosis and syphilis, which helped confirm outbreaks and aided decisions over isolation and contact-tracing. Some laboratories became significant vaccine and antiserum production factories; indeed, the move that many made to greenfield sites was to provide facilities for keeping large animals rather than creating a conducive environment for scientific creativity. The subject was also aided in the 1900s by the vogue for therapeutic bacterial vaccines. The aim of this treatment was to boost the immunity of those already sick by inoculating patients with appropriately modified bacteria. It was assumed to be particularly valuable in localized infections where the full immune system might not have been mobilized. The treatment was pioneered in hospitals, where bacteriologists would often produce a vaccine made from bacteria taken from the patient; however, this method was expensive and soon vaccines were being mass produced by commercial laboratories. Vaccine therapy was largely abandoned before 1920, but it had a major impact on the development of bacteriology in hospitals and further attracted commercial companies to the subject. Indeed, at this time the pharmaceutical industry

was often spoken of as consisting of two types of operation — chemical and biological — with the latter specializing in bacteria-related products. See also **Vaccines** and **Vaccine Technology**.

After 1900, medical bacteriology became more technically sophisticated. In the first instance, this was because of the development of work on viruses, then termed 'filterable viruses' or 'ultramicroscopical viruses', defined by their physical rather than biological properties. Bacteriologists had found the microorganisms responsible for many diseases, but several had still eluded researchers by 1900. The best known were smallpox (variola), cowpox (vaccinia), measles, poliomyelitis and influenza. However, in the late 1890s and early 1900s methods were devised to detect, isolate and experiment with organisms that were too small to be seen with microscopes or to be isolated by physical methods. However, it took scientists until the 1930s before there was sufficient mastery of viruses for vaccines to be produced, as with yellow fever in 1936. A second factor that complicated medical bacteriology was that bacteria turned out to be more variable and complex than at first thought. Some groups, like the *Rickettsia*, responsible for typhus and spotted fever, were found to have a bacterial form but to behave like viruses, and to be spread by insect vectors. More important was the finding that the bacteria of many common diseases, such as pneumonia and septic infections, could exist as different types or strains. See also **Influenza**; **Measles**; **Virology (The History)**; and **Yellow Fever**.

Those scientists pursuing medical studies of bacteria were interested in three problems: (1) the identification of microorganisms to aid diagnosis; (2) finding ways to destroy microorganisms in the body or outside; and (3) using altered microorganisms to stimulate the human immune system. In the 1920s and 1930s, bacteriologists felt they had made excellent progress with diagnosis, though they were less confident with vaccines, as promising developments, such as with the BCG vaccine for tuberculosis, continued to be affected by technical difficulties and social resistance. The mid-1930s saw further technical innovations that advanced work on viruses, notably the electron microscope and live culturing, which in time were the basis for the establishment of virology apart from its parent specialism. However, far less had been achieved with the treatment of bacterial diseases. Vaccine therapy had been abandoned and selective chemical poisons (so-called *magic bullets*), which killed bacteria yet were harmless to human cells as with Salvarsan therapy for syphilis, proved difficult to find or make. Indeed, the side effects of many treatments proved worse than the disease. There were claims in the 1930s that the medical influence on bacteriology had been damaging, leading to a skewed research program that had ignored basic questions such as bacterial physiologies, their genetics and their evolution. Biologists suggested that more fundamental research would help generate new ideas to be exploited in applied areas such as therapeutics. See also **Electron Microscope**.

Such calls were soon ignored, because in 1936 the introduction of sulphonamide drugs revived the prospects of chemotherapy and within a decade the development of penicillin had revolutionized medicine and bacteriology. Sulphonamide drugs, developed by Gerhard Domagk, had an immediate impact on the treatment of puerperal fever and pneumonia, bringing down death rates dramatically. However, the major consequence was to stimulate the search for other organisms with antibacterial properties, which led to the recognition of the value of penicillin and then other naturally occurring antibiotics, such as streptomycin. The scale and political importance of these developments during and after World War II ensured that there was increased investment in the study of bacteria, from their biochemistry and genetics, up to their ecological relationships. On a different front, governments became aware of the potential of biological weapons, particularly the use of aerosols to spread bacterial toxins, spores and organisms themselves. Weapons carrying anthrax spores offered most promise as a means to damage livestock industries and food supplies, rather than causing direct human casualties. See also **Antibiotics**; **Domagk, Gerhard Johannes Paul (1895–1964)**; and **Penicillin**.

Nonmedical bacteriology continued to develop, albeit growing more slowly and in diverse settings. In agricultural bacteriology, dairying and tuberculosis continued to dominate, though the interwar years saw the growth of plant pathology and soil science, in which bacteriologists played an important part. Bacteriologists were also employed to work on specific problems, especially the deterioration of foodstuffs and natural products. The use of fermentation to produce alcohols on a commercial scale for industrial uses was tried during World War I as one of the many programs to overcome shortages in raw materials. However, at the end of hostilities work ceased, or rather continued experimentally without large-scale applications. Indeed, the full potential of bacterial production was not fully realized until the emergence of biotechnology in the final decades of the twentieth century.

BACTERIOPHAGE. A bacteriophage is a virus that infects a bacterial cell. The name, usually shortened to *phage*, means *eater of bacteria* and was coined by Felix d'Hérelle in recognition of the ability of the viruses he studied to lyse infected bacterial cells. The word *bacteria* is used here as a general term for microorganisms in the domains Bacteria (eubacteria) and Archaea (archaebacteria).

Discovery

In 1915 and 1917, Frederick W. Twort, in London, and Felix d'Hérelle, in Paris, independently described viruses that destroyed bacteria. Twort published a single note on his observations and went on to other research, while d'Hérelle began years of studies on the nature of bacterial viruses. d'Hérelle's findings included development of the plaque assay for quantitating phages and description of the phage replication cycle, and was the beginning of modern virology. See also **Virology (The History)**.

Hosts

The range of hosts that can be infected by a particular phage is determined by which bacteria have specific sites for attachment of that phage and by the ability of the phage genome to enter and replicate in those bacteria. Some phages are extremely specific and infect only a single bacterial strain. Many phages infect phylogenetically closely related bacterial strains or species. Other phages infect bacteria in different genera, although these genera are usually phylogenetically related, e.g. enterobacteria.

Techniques

The presence of phages in a sample is most easily demonstrated by the ability of viable phages to infect and propagate in bacterial host cells. Experimentally, this is generally observed by spreading the putative phage-containing sample on a bacterial lawn growing on a solid medium (i.e. a layer of agar-containing culture medium in a Petri dish) and, after appropriate incubation conditions, looking for clear areas in the lawn. These clear areas, called *plaques*, result from the initial infection of a bacterial cell by a single viable phage, intracellular production of progeny phage and their release by cell lysis, and subsequent rounds of infection and lysis of nearby host cells in the lawn by nascent progeny phages. Hence, although a plaque is produced by the lysis of many infected cells, all phages in the plaque are the progeny of the single initial infectious phage, and phage titres are usually measured as "plaque-forming units" (PFUs).

Isolation

Phage isolation requires a liquid sample that can be spread on lawns of possible bacterial host cells to produce plaques. Liquid specimens (e.g., sewage and marine samples) can be spread directly on bacterial lawns. Solid samples (e.g., soil, and plant and animal material) must be dispersed in liquid (either buffer or culture medium) before spreading. Solids and, in the case of nonsterile samples, contaminating microbial cells must be removed before spreading, usually by filtration through a 0.45-μm pore-size filter.

Phage titres in most environmental samples may be so low that direct spreading yields no plaques. Such samples first must be either enriched using biological methods (i.e., infection of bacteria in liquid culture) or concentrated using physical (e.g., centrifugation) or chemical (e.g., separation by partitioning using an immiscible agent like polyethylene glycol) methods.

Propagation and Maintenance

Most phages are propagated by infection of exponentially growing bacteria in liquid media, with incubation conditions (e.g. media, temperature and oxygen concentration) and times chosen to produce large progeny phage titres. However, some phages propagate best in bacteria growing on solid media. In these cases, phages are spread on bacterial lawns, incubated using appropriate conditions and progeny phages are harvested by washing. Phages in liquid or solid media are separated from cell debris and sterilized, usually by filtration through 0.45-μm pore-size filters. Concentration may be achieved by physical and chemical methods, as noted above.

Long-term maintenance of viable phage samples requires different conditions for different phages. The most useful methods have been storage at 4 °C (39 °F) or in liquid nitrogen or in lyophiles.

Identification

Electron microscopy is the best initial method for phage identification because it enables the taxonomic family to be determined or at least narrowed down. Other important properties for phage classification are host range, nucleic acid structure (e.g. deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), single-stranded or double-stranded, and linear or circular). A variety of other properties have been used for studying closer taxonomic relationships, e.g. DNA–DNA hybridization, nucleic acid sequence similarities, serological cross-reactivity, DNA replication and packaging mechanisms and protein composition. See also **Electron Microscope**.

Classification

A system for phage classification has been developed by the International Committee on Taxonomy of Viruses over the past few decades. Phages are currently (as of early 2005) classified in 14 families and 1 unassigned genus (Table 1). The three families of tailed phages have been grouped in the order *Caudovirales*. Other bacterial virus taxa contain phages with polyhedral, filamentous or more complex symmetry. In virus taxonomy, the name of an order ends in *-virales*, a family ends in *-viridae* and a genus ends in *-virus*. Most phage genera have been assigned latinized names. However, thus far tailed phage genera have only been assigned vernacular names because of uncertainties regarding the necessary and sufficient parameters for defining these taxa. In each genus, a species for which considerable data are available is designated the type species.

Distribution in the Bacterial World

Phages that infect hosts in about 140 bacterial genera, including genera on most major eubacterial and archaebacterial phylogenetic branches, have been identified as of early 2000. As more diverse bacteria are studied, it is expected that most (if not all) eubacterial genera will be found to be hosts for one or more phages.

Virion Properties

The morphology of phage virions or particles has been determined largely by electron microscopy of negatively stained and frozen-hydrated samples. These results have been supplemented with data on the atomic structure of some phage capsids, virion composition and physical and chemical properties.

Morphology

As of late 2000, about 5100 phages have been reported, with 96% (about 4950 phages) having tailed phage morphology and 4% (186 phages) with polyhedral, filamentous or pleomorphic morphology. Tailed phages have a protein head, containing a genome of linear, double-stranded DNA and a protein tail that functions in phage–host cell attachment and DNA injection. The structure of phage heads is based on either an icosahedron (a polyhedron with 20 faces, each an equilateral triangle and 12 vertices) or an elongated icosahedron. Three types of phage tails have been found: 25% of tailed phages have long, contractile tails; 61% have long, noncontractile tails; and 14% have short, noncontractile tails.

TABLE 1. TAXONOMY OF BACTERIOPHAGES

Double-stranded (ds) DNA viruses
Order: *Caudovirales* (tailed phages, genome linear dsDNA)
- Family: *Myoviridae* (contractile tails)
  - Genus: 'T4-like viruses'
    - Type species: *Enterobacteria phage T4*
  - Genus: 'P1-like viruses'
    - Type species: *Enterobacteria phage P1*
  - Genus: 'P2-like viruses'
    - Type species: *Enterobacteria phage P2*
  - Genus: 'μ-like viruses'
    - Type species: *Enterobacteria phage* μ
  - Genus: 'SP01-like viruses'
    - Type species: *Bacillus phage SP01*
  - Genus: 'ΦH-like viruses'
    - Type species: *Halobacterium phage ΦH*
- Family: *Siphoviridae* (long noncontractile tails)
  - Genus: 'λ-like viruses'
    - Type species: *Enterobacteria phage* λ
  - Genus: 'T1-like viruses'
    - Type species: *Enterobacteria phage T1*
  - Genus: 'T5-like viruses'
    - Type species: *Enterobacteria phage T5*
  - Genus: 'L5-like viruses'
    - Type species: *Mycobacterium phage L5*
  - Genus: 'c2-like viruses'
    - Type species: *Lactococcus phage c2*
  - Genus: 'ΨM1-like viruses'
    - Type species: *Methanobacterium phage ΨM1*
  - Genus: 'ΦC31-like viruses'
    - Type species: *Streptomyces phage ΦC31*
  - Genus: 'N15-like viruses'
    - Type species: *Enterobacteria phage N15*
- Family: *Podoviridae* (short noncontractile tails)
  - Genus: 'T7-like viruses'
    - Type species: *Enterobacteria phage T7*
  - Genus: 'P22-like viruses'
    - Type species: *Enterobacteria phage P22*
  - Genus: 'Φ29-like viruses'
    - Type species: *Bacillus phage Φ29*
  - Genus: 'N4-like viruses'
    - Type species: *Enterobacteria phage N4*
- Family: *Tectiviridae* (lipid-containing, double icosahedral capsids, genome linear dsDNA)
  - Genus: *Tectivirus*
    - Type species: *Enterobacteria phage PRD1*
- Family: *Corticoviridae* (lipid-containing, icosahedral capsid, genome circular dsDNA)
  - Genus: *Corticovirus*
    - Type species: *Pseudoalteromonas phage PM2*
- Family: *Plasmaviridae* (enveloped, pleomorphic, genome circular dsDNA)
  - Genus: *Plasmavirus*
    - Type species: *Acholeplasma phage L2*
- Family: *Lipothrixviridae* (enveloped, filamentous or rod-shaped, genome linear dsDNA)
  - Genus: *Alphalipothrixvirus*
    - Type species: *Thermoproteus tenax virus 1*
  - Genus: *Betalipothrixvirus*
    - Type species: *Sulfolobus islandicus filamentous virus*
  - Genus: *Gammalipothrixvirus*
    - Type species: *Acidianus filamentous virus 1*
- Family: *Rudiviridae* (nonenveloped, rod-shaped, genome linear dsDNA)
  - Genus: *Rudivirus*
    - Type species: *Sulfolobus islandicus rod-shaped virus 2*
- Family: *Fuselloviridae* (lipid-containing, lemon-shaped, genome circular dsDNA)
  - Genus: *Fusellovirus*
    - Type species: *Sulfolobus spindle-shaped virus 1*
- Family: *Guttaviridae* (droplet-shaped, genome circular dsDNA)
  - Genus: *Guttavirus*
    - Type species: *Sulfolobus newzealandicus droplet-shaped virus*

(*continued*)

TABLE 1. (*Continued*)

Unassigned genus *Salteroprovirus* (lemon-shaped with short tail, genome linear dsDNA)
Type species: *His1 virus*
Single-stranded (ss) DNA viruses
Family: *Inoviridae* (nonenveloped, filamentous or rod-shaped, genome circular ssDNA)
Genus: *Inovirus*
Type species: *Enterobacteria phage M13*
Genus: *Plectrovirus*
Type species: *Acholeplasma phage L51*
Family: *Microviridae* (nonenveloped, icosahedral, genome circular ssDNA)
Genus: *Microvirus*
Type species: *Enterobacteria phage ΦX174*
Genus: *Spiromicrovirus*
Type species: *Spiroplasma phage SpV4*
Genus: *Bdellomicrovirus*
Type species: *Bdellovibrio phage MAC1*
Genus: *Chlamydiamicrovirus*
Type species: *Chlamydia phage Chp1*
Double-stranded RNA viruses
Family: *Cystoviridae* (enveloped, icosahedral, genome segmented linear dsRNA)
Genus: *Cystovirus*
Type species: *Pseudomonas phage Φ6*
Positive-sense, single-stranded RNA viruses
Family: *Leviviridae* (nonenveloped, icosahedral, genome linear ssRNA)
Genus: *Levivirus*
Type species: *Enterobacteria phage MS2*
Genus: *Allolevirus*
Type species: *Enterobacteria phage Q β*

Of the nontailed phages, 57% have polyhedral morphology, 35% filamentous morphology and 8% pleomorphic morphology. The polyhedral phages that have been studied are icosahedra, either naked or enveloped, with a protein shell or capsid containing the phage genome, which can be either single- or double-stranded DNA or RNA. Filamentous phages can be rigid or flexible protein filaments with helical symmetry, either naked or enveloped, containing a single-stranded DNA genome. A small number of phages with pleomorphic morphologies (all containing genomes of double-stranded DNA) have been described, each having evolved to infect a novel type of host: enveloped, quasispherical virions infect mycoplasmas and lemon- and droplet-shaped virions infect archaebacteria.

The range of phage morphologies reflects selection for virions able to infect diverse bacterial taxa and package different types of nucleic acids. Phages must attach and inject their genomes through a wide range of cell surfaces, including Gram-positive and Gram-negative eubacterial cell walls, chlamydial outer membranes mycoplasmal cell membranes and archaebacterial cell walls.

Physical and Chemical Properties

Phage genomes can be single- or double-stranded, linear or circular, DNA or RNA molecules. With one exception, phage genomes are single molecules. The exception is the cystoviruses, which infect pseudomonads and have a segmented genome consisting of three molecules of linear double-stranded RNA. Phage genome sizes range from the leviviruses, with genomes about 3.5 kb (encoding 3–4 gene products), to the larger tailed phages, with genomes of several hundred kilobases (encoding hundreds of gene products). Many phage genome sequences have been determined and are available in databases (e.g., GenBank).

Paralleling the genome diversity of phages, their structural complexity ranges from the leviviruses, small icosahedral virions composed of 180 molecules of a coat protein and one molecule of an attachment protein, to the larger tailed phages, with virions of at least 40 different proteins, each present from a few copies to hundreds of copies.

In addition to morphology and composition, a variety of physical and chemical properties have been measured for phage virions. Such studies have included X-ray diffraction and spectroscopic measurements to analyze virion molecular structure; sedimentation analysis to determine virion shape, size and hydrodynamic properties and sensitivity to inactivation by physical (e.g. heat and ultraviolet light) and chemical agents (e.g. lipid solvents and pH) to probe virion structure and genome repair capabilities.

Replication

The process in which a phage infects a bacterial cell and produces progeny virions is called the lytic, vegetative or productive cycle –lytic because, for most phages, infected cells must lyse to release progeny phages. In certain intracellular physiological situations, some phages do not replicate and instead produce latent infections. This is called the *lysogenic cycle* and latently infected cells are called lysogens. Phages that only produce a lytic infection are called *lytic* or *virulent* phages. Phages that can produce either a lytic or a lysogenic infection are called lysogenic or temperate phages.

Lytic Cycle. The steps in a lytic phage infection are attachment (or adsorption), penetration (or injection), multiplication (or replication), assembly and packaging (or maturation) and release.

Attachment (adsorption). Attachment begins with random collisions between a phage and a bacterial cell, leading to specific interactions between virion and cell surface components. These cell components are called *receptors* and are normal constituents of cell wall polysaccharides, pili or flagella. Different phages adsorb to different specific bacterial receptors.

Penetration (injection). Penetration is the entry of the viral genome (and, in some cases, virion proteins) from an adsorbed virion into a host cell. Although virions of a few of the smaller phages penetrate the cell wall, only viral nucleic acid enters the cytoplasm. Penetration of Gram-negative bacteria by tailed phages has been shown, for a few phages, to involve fusion of the bacterial outer and inner membranes, induced by the adsorbed phage tail, followed by DNA injection. However, for most phages, the mechanism by which viral nucleic acid passes from the virion through the cell surface and into the cytoplasm is not understood.

Multiplication (Replication). Multiplication requires expression of the injected virus genome to take over the host cell's biosynthetic machinery for synthesis of the viral nucleic acids and proteins needed to assemble progeny virions. Phages with small DNA genomes (and, hence, limited coding capacity) use host cell DNA and RNA polymerases for DNA replication and transcription, while phages with large DNA genomes (and, hence, greater coding capacity) generally encode phage DNA and RNA polymerases. RNA phages encode an RNA-dependent RNA-polymerase (also called a *replicase* or *transcriptase*) for phage RNA replication and transcription.

There is no temporal regulation of gene expression for small phage genomes: essentially all phage genes begin to be transcribed and translated soon after injection, and continue to be expressed throughout infection. In contrast, multiplication of phages with large DNA genomes requires temporal regulation of phage macromolecular syntheses, usually occurring in three phases: synthesis of early gene products, then of progeny virus DNA and finally of late gene products. Phage early gene products shut down the host cell's DNA, RNA and protein syntheses, adapt cellular biosynthetic machinery for phage syntheses and start phage DNA replication. Late genes encode the products required for assembly of progeny phage virions.

Assembly and Packaging (Maturation). The formation of progeny phage virions from nascent phage structural components is by self-assembly, frequently involving scaffolding or other morphogenetic proteins and specific proteolytic cleavages of structural proteins by phage-encoded proteases to induce conformational changes and form new binding sites for further assembly. In most phage assembly processes, progeny virus nucleic acid is packaged into almost completed capsids, thereby assuring that progeny genomes are packaged into correctly assembled structures. However, in some phage assembly processes, the capsid is assembled around, or coassembled with, progeny virus genomes. For tailed phages with large DNA genomes, heads and tails are assembled in independent pathways, DNA is packaged and only then are the completed heads and tails joined, assuring both that progeny DNA is packaged in correctly assembled heads and that tails only go on to heads containing correctly packaged DNA.

Release. Release of most progeny phages requires bacterial cell lysis. In these cases, a virus gene product is produced that gradually hydrolyses the host cell peptidoglycan structure, thereby weakening it enough so that internal cell osmotic pressure can eventually cause cell lysis. The exceptions to release by cell lysis are filamentous phages, which are released by extrusion through host cell membranes, and mycoplasmal phages, which are released by budding from their wall-less host cells. Productive infections lead to release of 20–1000 progeny phages per infected cell, depending on the specific phage and cell growth conditions.

Lysogenic Cycle. Most phages are temperate and can produce either lytic or lysogenic infections. For these phages, after adsorption and penetration, a temperate phage early gene product is affected by the cell's intracellular physiological condition. If intracellular conditions (e.g., adenosine triphosphate (ATP) and amino acid concentrations) are not adequate for a productive phage infection, the phage early gene product induces synthesis of a phage repressor protein. This repressor blocks further synthesis of phage genes and a latent infection, called lysogeny, is established. The latent phage genome is called a *prophage*. Most prophage genomes are integrated into the host cell's chromosome, but a few persist as plasmids. In either case, prophages replicate along with the cell genome and a lysogen produces a clone of cells, each containing a prophage.

The lysogenic state can continue indefinitely. However, if the host cell encounters a potentially lethal situation (e.g. damage to the cell chromosomal DNA), most prophages undergo induction and produce progeny phages. This occurs because, as the cell activates its DNA repair genes, the new intracellular conditions lead to degradation of the repressor, which allows synthesis of phage genes to begin, eventually leading to production of progeny phages and cell lysis. For prophages integrated in the cell chromosome, induction begins with excision of the phage genome from the cell genome. Induction can also occur spontaneously at low frequency, so most cultures of lysogenic bacteria contain free phages produced by the small fraction of spontaneously induced lysogens in the culture.

Some temperate phages carry genes that can change the phenotype of a lysogenized bacterial cell. These genes are expressed from the integrated prophage genome and can affect host cell surface properties (e.g. *Salmonella phage* ε can carry a gene that changes the structure of the host cell's outer membrane lipopolysaccharide) or pathogenicity (e.g. *Corynebacterium phage* ε can carry the diphtheria toxin gene).

Other Types of Host-Virus Relationship. There are two types of persistent phage infection distinct from lysogeny: pseudolysogeny and steady state infection. Pseudolysogeny occurs when only some cells in a culture are infected, so the culture contains phage-infected cells and uninfected cells. This situation can arise if the host cell culture is a mixture of cells with different sensitivities to phage infection. Steady state infection occurs when all cells are infected by a noncytocidal phage (e.g. filamentous phages that are released by extrusion), so all cells continue to grow, although usually more slowly compared with uninfected cells, while releasing progeny phages.

Ecology

Since viruses are obligate intracellular parasites, the habitats of phages are bacteria and phage ecological diversity reflects bacterial ecological diversity. Therefore, phages are found wherever bacteria are found. Bacteria are ubiquitous in the biosphere, growing on the surfaces of and within plants and animals, in biofilms on many organic and inorganic materials, in diverse terrestrial and aquatic habitats and in a variety of extreme environments (e.g. thermophiles and psychrophiles, acidophiles and alkaliphiles, halophiles, xerophiles and barophiles). Lysogenic bacteria are generally distributed in all these habitats and, because of spontaneous induction, free phages are usually present as well.

Phage titres in most natural habitats are low but there are exceptions in a few ecosystems where bacterial titres are high: phage titres can reach 10^9 PFU g^{-1} in human faeces and 10^7 PFU mL^{-1} in sewage. On a global scale, the number of phages is enormous: the biosphere contains about 10^{30} prokaryotes and, since environmental samples have about 10 times more tailed phages than bacteria, the biosphere must contain at least 10^{31} phages.

Recent studies have identified bacteria in many habitats that have not, as yet, been able to be cultivated in the laboratory. These data indicate that only a few per cent of bacterial species in natural habitats can be cultivated using current methods. Therefore, since phages are presently recognized by their ability to form plaques on lawns of cultivated bacteria, it will be interesting to see whether future studies of uncultivated bacteria identify new phage taxa.

Plasmids, Episomes and Bacteriocins

Several types of genetic elements and gene products, other than phages, are found in some bacteria. Plasmids are extra chromosomal double-stranded DNAs that replicate independently of the bacterial chromosome and regulate their replication so the number of plasmid copies per cell is relatively constant. A plasmid can be a circular or linear DNA molecule, vary in size from a few to hundreds of kilobase pairs, and have a copy number ranging from one to several hundred per cell. Depending on its size, plasmids encode from a few to hundreds of gene products and, although plasmid-encoded gene products are rarely essential for bacterial growth, some provide the cell with a selective advantage for growth in particular situations. See also **Plasmid**.

Some plasmids can exist either as extrachromosomal DNAs or integrated into the cell chromosome. Such genetic elements, that can exist either autonomously in the cytoplasm or integrated in the cell chromosome, are called *episomes*. The terms *plasmid* and *episome* are sometimes used interchangeably.

One type of plasmid-encoded gene product in some bacteria is a bacteriocin, an agent that is toxic for related bacteria. Therefore, bacteriocins provide the bacteria that produce them with a selective advantage against other bacteria trying to grow in the same ecological niche.

Origin and Evolution

Genome sequences of many viruses and cells have recently become available. Analysis of these data indicate phylogenetic relatedness between viruses within many families (and, in some cases, between virus families within orders) and between virus and cell genes. Hence, the generally accepted model for the origin of viruses is that mobile genetic elements capable of autonomous replication (such as plasmids, episomes, transposons and retrotransposons) acquired the cell genes that gave them an extracellular infectious capability, enabling them to be horizontally transmitted between cells. Virus evolution would have then proceeded by point mutations, insertions, deletions and changes in reading frames. Recombination and reassortment would have led to modular evolution, in which gene domains or contiguous genes move between virus genomes and between virus and cell genomes. Questions remain about whether there was one or more origins of viruses; in particular, whether there was a single origin for RNA and DNA viruses, and whether RNA viruses may be descendants of the "RNA World" hypothesized to have been the precursor to cells with DNA-based genomes.

Phages probably evolved with their bacterial hosts aeons before the evolution of eukaryotes. Since tailed phages infect cells in the domains Bacteria and Archaea, tailed phages probably evolved early in cellular evolution, perhaps before these two domains diverged from their common ancestor, but definitely before the eubacterial and archaebacterial biosynthetic machinery diverged significantly. The double-stranded DNA genomes of tailed phages are mosaics of virus and cell genes, presumably the result of modular evolution with horizontal transfer of genes between phage genomes and between phage and bacterial genomes. There has been less phylogenetic analysis of phages with polyhedral, filamentous and pleomorphic morphology but, because their hosts are usually obligate or facultative aerobes, these types of phages may have evolved more recently, after the evolution of an oxygen-containing atmosphere.

Applications

Phages have been used as tools in molecular biology and biotechnology, antibacterial agents, markers and test objects and reagents for typing bacteria. In addition, phages are significant contaminants in a number of industrial processes.

Phages were important experimental organisms in the origin and development of molecular biology, and continue as essential systems in many aspects of molecular biology and biotechnology. For example, several tailed phages with double-stranded DNA and their derivatives (e.g. phages λ, P1 and μ and constructs containing parts of phage λ and plasmid DNAs) are major cloning vectors; filamentous phages with single-stranded DNA (e.g. phage M13 and its variants) have been genetically engineered to serve as cloning vectors, DNA sequencing templates and vectors for phage display (i.e. expression of cloned peptides for selection and cloning) and phage μ, in which replication involves integration of double-stranded μ DNA into the host cell's genome, is used for random mutagenesis and gene transfer.

D'Hérelle originally recognized the possibility of using phages as therapeutic antibacterial agents for certain diseases. Experiments at that time and into the 1920s were popularized in Sinclair Lewis's 1924 novel *Arrowsmith*. The controversial results of phage therapy kept this approach from being adopted in most countries, and the advent of antibiotics in the 1940s generally eliminated interest in this type of therapy. However, phage therapy continued to be studied and used in France, Poland and parts of the

former Soviet Union. In the past few years there has been renewed interest in evaluating phage therapy, as the work from Eastern Europe has become known and translated into English and as antibiotic-resistant bacteria have become a growing threat to public health.

The small size of phage particles and the sensitivity of phage assays (a single phage can be detected as a plaque-PFU) have made phages useful markers and test objects for a variety of industrial applications. These include measuring disinfectant efficacy, evaluating air filter and aerosol sampling capacities and monitoring water movements in natural environments.

Phage typing was an early epidemiological tool for classifying bacteria. Sets of typing phages were established for many human, animal and plant pathogenic bacteria. In practice, samples of phages from a typing set were spotted on lawns of bacteria of interest and, after incubation, bacteria were classified based on their resistance to infection by members of the phage set. Phage typing has been replaced almost completely by a variety of molecular methods for bacterial epidemiology (e.g., determination of molecular markers like antibiotic resistance and plasmid profiles).

Finally, although not a desired application, phages are important contaminants in a number of industrial microbial fermentation processes; for example, production of antibiotics, organic solvents and dairy products. Phage contamination leads to abnormal fermentations and can cause significant economic losses. A variety of strategies (e.g. production conditions to minimize contamination and rotation of microbial cultures) are used to prevent and control phages in these industries.

BAD LANDS. The literal translation of the phrase *Mauvaise Terre* of the French explorers who so described the highly dissected, relatively unconsolidated sandstones and shales such as occur in the western Great Plains near the Black Hills. Small areas also occur in the plateaus of the Rocky Mountain region. This type of topography develops in arid and semi-arid regions where the underlying formations are relatively soft, and, due to the climate, are not protected by a plant cover.

BAEKELAND, L. H. (1863–1944). Born in Ghent, Belgium. He did early research in photographic chemistry and invented Velox paper (1893). After working for several years in electrolytic research, he under took fundamental study of the reaction products of phenol and formaldehyde, which culminated in his discovery in 1907 of phenol-formaldehyde polymers originally called "Bakelite." The reaction itself had been investigated by Bayer in 1872, but Baekeland was the first to learn how to control it to yield dependable results on a commercial scale. The Bakelite Co. (now a division of Union Carbide) was founded in 1910.

BAEYER, JOHANN FRIEDRICH WILHELM ADOLF VON (1835–1917). The son of a Prussian military officer, Baeyer was born in Berlin and studied chemistry with R. Bunsen and A. Kekulé at the University of Heidelberg. He taught organic chemistry at the Technical School in Berlin (1862–1872) and at the University of Strasbourg (1872–1875) before succeeding J. Liebig at the University in Munich, where he spent the rest of his career. A brilliant director of research, he taught a large number of outstanding organic chemists, including the Nobel Prize winners E. Büchner, E. Fischer, H. Willand and R. Willstätter. The king of Bavaria ennobled him in 1885. See also **Buchner, Eduard (1860–1917)**; and **Fischer, Emil Hermann**.

In 1905 he was awarded the Nobel Prize in Chemistry for the synthesis of the natural dyestuff, indigo, in 1880. The synthesis, which was subsequently developed commercially by the Badische Anilin- und Soda-Fabrik (BASF), destroyed the economy of agriculturally produced indigo and confirmed the ability of organic chemists to synthesize natural products. See also **Indigo**. Although primarily an empirical organic chemist, Baeyer developed an influential explanation of the structure of heterocyclic compounds that involved the idea that the normally tetrahedrally directed valences of carbon atoms are put under strain when forming a closed ring. The theory, the beginning of conformational analysis, has had wide applications in the twentieth century in understanding the structures of molecules involved in living processes. Baeyer also investigated uric acid derivatives, phthalein dyes and condensation reactions. In 1870 he proposed that photosynthesis was a photochemical reaction in which water and carbon dioxide formed oxygen and formaldehyde, the latter condensing to form carbohydrates.

BAFFIN CURRENT. See **Ocean Currents**.

BAFFLE. An object, usually a partition, placed for some specific purpose in the flow path of a fluid, causing the fluid to take some prearranged and circuitous path. Thus, baffles are found in steam boilers to direct the hot gas properly back and forth over the tubes so that the gas will give up its heat to the required degree and will not short-circuit directly from the furnace to the stack. For this service the baffle is composed of refractory material similar to firebrick and will be found in longitudinal or transverse arrangement. Transverse baffling is made by building the baffle perpendicular to the tubes. Longitudinal baffles are usually precast and laid upon the tubes of the boiler, forming a baffle whose surface is parallel to the tubes.

Baffles are built in coagulation basins to impede the flow of liquids, and are also found in exhaust mufflers, where their purpose is to mix the flow of gases in adjacent exhaust puffs so that they may emerge from the muffler in a silent steady stream.

BAGASSE. In the manufacture of sugar from sugar cane, the crushed fibers from which the sap has been expressed are called bagasse. Its principal use is as a fuel to run the mills that crush the cane. For this purpose bagasse is mixed with petroleum oil. It is also used as a fertilizer and to some extent in manufacturing heavy insulation board and coarse paper.

BAGELS AND PRETZELS. See **Bakery Processes, Yeast-Raised Products**.

BAG-WORM *(Insecta, Lepidoptera).* The larva of a moth encased in a covering of silk mixed with bits of leaves, twigs, etc. Only the head and legs protrude from the bag, hence the insect appears to be suspended from the twig on which it walks. The adult females are wingless and the eggs are deposited in the silken bag.

One species of bag-worm sometimes does great damage to evergreen trees, especially the cedars, and so has been named the evergreen bag-worm, *Thyridopteryx ephemeraeformis*. The larvae can be killed by spraying infested trees with control chemicals and the destruction of the bags in the winter, when they contain eggs, is an important measure of control.

These insects constitute the family *Psychidae*.

BAI. See **Meteorology**.

BAILY BEADS. During an eclipse of the sun, at the instant when the moon's edge is just tangent to the edge of the sun, i.e., at either second or third contact, the thin crescent of the disappearing sun suddenly breaks up into a number of brilliant spots known as Baily beads. These are produced because the surface of the moon is very rough, and mountains on the moon will completely cover the sun's disk while the sunlight is still coming to the earth through the valleys.

BAINITE. A product of the decomposition of austenite that usually occurs at temperatures between those that produce pearlite and those that produce martensite. Its structure consists of finely divided carbide particles in a matrix of ferrite.

BAI-U. See **Meteorology**.

BAKERS'S YEAST (SACCHAROMYCES CEREVISIAE). See **Bakery Processes, Yeast-Raised Products**.

BAKERY PROCESSES, CHEMICAL LEAVENING AGENTS. See **Leavening Agents**.

BAKERY PROCESSES, YEAST-RAISED PRODUCTS. The U.S. baking industry comprises an important portion of the food industry, the nation's largest business. Another source of bakery foods is the food service industry, establishments, including restaurants, hospitals, and prisons. Differentiated from the quickly perishable bakery foods are the dry bakery products such as cookies, crackers, pretzels, and ice cream cones. These latter items possess a much longer shelf life and may be distributed over a wider area from typically very large manufacturing facilities. Average per capita consumption of all bakery products in the United States was over 50 kg (110 lbs). Bread accounted for about 45% of this consumption, while all yeast-leavened items comprised approximately 74% of the total.

Bread and other yeast-raised bakery foods are widely consumed and desired, in part, because of their appealing flavor and light, porous texture, properties which depend largely on yeast fermentation. Leavening by the action of yeast was known to the Egyptians as early as 2000 BC; mummified yeast-raised loaves have been found in early Egyptian tombs as well as in the Roman ruins of Pompeii. The Hebrews also understood the art of leavening, presumably by yeast, because laws concerning the use of both leavened and unleavened bread are given in the book of Exodus in the Bible.

The role of baker's yeast (*Saccharomyces cerevisiae*) in producing leavened bread depends on two factors: the ability of yeast to generate carbon dioxide and alcohol through the breakdown of simple sugars, and the unique ability of wheat flour proteins to form films in dough that trap evolved gases. Basic bread is made with flour, water, salt, and yeast. See also **Fermentation**; and **Yeasts and Molds**. Product variety is achieved by incorporating varying amounts of additional ingredients; by altering the breadmaking process; by shaping or cutting or putting toppings on the dough prior to baking; or by the method of baking. Each of these practices may be utilized alone or in combination to produce a virtually limitless number of yeast-raised products. Thus raisin bread is made from a white-type bread dough with the addition of raisins and possibly spice. French bread is made from a lean white dough, shaped into a cylinder and baked on the hearth of a steam-filled oven. Pita bread is also made from a lean white dough, but it is shaped into thin, round pieces before baking in a very hot (400 °C (752 °F) oven, to achieve the typical pocket formation. Sweet roll doughs are made with relatively high levels of sugar, fat, eggs, and yeast, compared to ordinary bread dough, and are shaped in various ways, with additional fillings and toppings to obtain the desired product.

Many other products belong to the category of yeast-raised bakery foods. Some that may be cited include various kinds of specialty breads, coffee cakes and danish pastries, bagels, croissants, yeast-raised doughnuts, some types of crackers, English muffins, and rolls. Of the total annual sales of the baking industry, yeast-raised goods constitute about 61%.

Chemical Leavening

Chemical leaveners (primarily baking powders) are utilized in cakes, cookies, some crackers, refrigerated dough, and quick bread manufacturing. These products make up roughly 39% of the value of the baking industry's total production. Both yeast and chemical leaveners are occasionally used together in the same formulation, for example in the production of certain frozen doughs. See also **Leavening Agents**.

Ingredients

A great many ingredients may be utilized in the production of innumerable bakery foods. The following discussion is limited to a relatively few key ingredients.

Flour. The primary ingredient of most bakery foods is wheat flour. This is especially true in breadmaking, where flour may comprise up to 95% of the ingredients, excluding water, in a lean bread dough. When the flour comes in contact with water in the dough, and mixing energy is applied, some of the proteins form elastic, gas-retaining films known as gluten. Mixing the dough is a critical processing step since it not only serves to distribute ingredients homogeneously, but also develops the gluten protein strands to a proper balance of viscoelastic properties that have the unique ability to retain fermentation gases in numerous small gas cells. During fermentation, the dough, which is tough and relatively elastic after mixing, mellows and becomes more extensible so that it is readily manipulated and shaped by appropriate machines and then baked into foods of good volume and quality.

The quality of flour used in the production of yeast-raised products depends on several factors, including the quality and characteristics of the wheat variety, the environmental conditions under which the wheat was grown, the skill of the miller in separating the endosperm of the wheat kernel from the germ and bran, and the proper treatment of the flour in the mill.

Flour quality analyses performed by the producer and user of flour include moisture, protein, ash, enzymatic activity, physical dough properties, and baking tests, all of which evaluate flour for specific end uses. The ash content of flour serves as an index of refinement. Enzymatic activity tests, which indirectly measure the effects of alpha-amylase on the hot-paste viscosity of flour suspensions, are estimated chiefly with the amylograph or Falling Number methods; optimum alpha-amylase activity in bread flour is important for overall quality and staling properties of bread. Physical properties of dough are generally evaluated by means of either the farinograph or mixograph. These instruments are small recording mixers which measure work input during mixing, and provide information such as mixing time, amount of water required (absorption) to yield a dough of appropriate consistency, mixing stability, and overall gluten strength.

Bread flours are primarily milled from hard red winter wheats grown in the Great Plains and hard red spring wheats grown in the north central region of the United States. See also **Wheat**. Most white pan breads are made with flour having a protein content of 11.0–12.5% (14% moisture basis). Certain products, such as mixed-grain or high fiber breads, or crusty hard rolls, may require stronger bread flours having about 1–2% higher protein. Clear flours, which are darker in color than typical bread flours but have a protein content of 13% or higher, are often used to bolster flour strength in nonwhite rye or wheat bread doughs.

Cake flours are produced from soft red or white wheats. Good quality cake flours are more highly refined than bread flours, and have lower ash and protein contents. Cake flours are usually treated with low concentrations of chlorine, which bleaches the flour and improves its baking performance such that higher amounts of sugar, shortening, and liquid may be used in formulations. The resulting "high ratio" cakes, which contain more sugar than flour, have good volumes, a fine grain, and tender, moist-eating properties. Soft wheat flours, less refined than cake flours, are used in the manufacture of biscuits, crackers, pies, and certain pastries. These flours are occasionally treated with chlorine gas in order to reduce spreading of certain cookies during production.

Yeast

Most of the yeast used by wholesale bakers is available in the form of fresh compressed yeast, granular, or as cream yeast (a slurry). Fresh or creamed yeasts are delivered at frequent intervals and refrigerated until used. Yeast fermentation leads to gas production which, in turn, leads to leavened dough and bread as well as the development of fermentation flavors. The quantity of yeast added to dough is directly related to the time required for fermentation. Currently, most bread doughs are made with 2–3% fresh compressed yeast, based on flour. This amount varies depending on the

form of yeast utilized. High sugar levels in sweet yeast-raised doughs tend to inhibit yeast activity through increased osmotic pressure and higher yeast levels are necessary to compensate.

Active dry yeasts of improved quality have been available for many years, and more recently instant active dry yeast has been introduced. This instant yeast exhibits more activity than regular active dry yeast due to improved drying techniques, and can replace compressed yeast at a rate of 33–40%. Dried yeasts, which are stable for long periods of time at room temperature, are of interest to bakers because of the high distribution cost of fresh compressed yeast. This is especially true for those away from distribution centers and for smaller bakers whose usage rate of yeast is low. See also **Yeasts and Molds**.

Yeast Foods

The so-called yeast foods are universally employed by wholesale bakers in quantities ranging from about 0.25–0.50% based on flour. Yeast foods are multifunctional proprietary materials, containing principally an ammonium salt, a calcium salt, and an oxidant. The only food in yeast foods is the ammonium ion, which serves as a source of nitrogen for the yeast. The bivalent calcium ion has a beneficial strengthening effect on the colloidal structure of the gluten, and the oxidizing agent has an improving action in dough through some largely unknown mechanism. A widely used yeast food is composed of 30% calcium sulfate, [CAS: 7778-18-9], 9.4% ammonium chloride, [CAS: 12125-02-9], 0.3% potassium bromate, [CAS: 7758001-2], 35% sodium chloride, [CAS: 7647-14-5], and 25.3% starch [CAS: 9005-25-8], or flour added as a filler.

Sugar

Sugar usage in white pan bread has increased over the years to a present concentration of about 8%, based on flour. Sugar is utilized to modify flavor, to help support yeast fermentation, and as a contributor to crust color and toasting properties through browning and caramelization reactions. High fructose corn syrups are predominantly used in bread production, although sucrose (cane or beet sugar) and corn syrups see some usage in breadmaking. In products requiring greater sweetness, sucrose is preferred. For frostings and fillings sucrose in the form of powdered sugars or fondant is the sweetener of choice because of its contribution to structure and its solubility properties. For cakemaking, sucrose is also preferred; replacement of sucrose in cake systems with high fructose corn syrup is limited because the latter causes flour starch to swell differently in a baking cake and it also leads to excessive browning. See also **Sugar**.

Shortening

Animal and vegetable fats and oils are used in many bakery foods to produce tenderness and to perform many other specific functions in the finished product. See also **Fats and Fatty Oils**; and **Vegetable, Oils (Edible)**. In breadmaking, fat addition yields a 20% volume increase besides improving keeping properties and tenderness. Fat usage has undergone considerable changes over the years; lard gave way to hydrogenated vegetable shortenings some years ago, and now liquid oils are mostly employed by wholesale bakers. Liquid soybean oil, used in conjunction with dough-strengthening surfactant systems, is economical, easily handled in bulk systems, and is desirable from a nutritional perspective. Fats in bread doughs have decreased from about 3–4% to 2–2.5%. Many cakes, icings, and fillings are made with specialty plasticized shortenings; however, wholesale snack cake bakers now widely use liquid soybean oil, which can make good quality cakes when employed with emulsifiers tending to form alpha crystals. Fluid shortenings, made with a base oil stock and small quantities of crystalline fat and surfactants, are also readily handled in bulk systems and are reported to yield superior quality bakery foods.

Butter is used in some, usually more expensive, bakery foods, and is prized for its flavor contribution. Fats are used in some products such as pie crust, croissants, or puff pastry, up to 60%, based on flour. Stability of fats and oils in perishable items such as breads, cakes, or pastries is of no consequence because shelf life is so limited that rancidity does not occur. In cookies and crackers, however, stable fats must be used in the formula since prolonged shelf life could lead to product deterioration with fats that develop rancidity.

A recent trend in the baking industry is to produce bakery foods with either no or reduced fat, to achieve perceived nutritional benefits. The functions of fat are achieved, to a degree, with materials such as maltodextrins and modified starches in combination with gums and emulsifiers. See also **Fat Replacers**.

Surfactants

Surfactants are widely used in bread and other bakery foods. In breadmaking, surfactants perform as crumb softeners or dough strengtheners, and they apparently do so by forming complexes. Monoglycerides, for example, complex with starch during baking to minimize subsequent retrogradation and staling, while ethoxylated monoglycerides complex with gluten proteins to provide strength. Other surfactants utilized in baking include sodium or calcium salts of fatty acids and lactic acid, polysorbates, succinylated monoglycerides, and diacetyl tartaric acid esters of monoglycerides. Surfactants are incorporated in cakes, icings, and fillings to promote emulsion stability, and to aid air incorporation and fat dispersion. See also **Emulsions**; and **Surfactants**.

Milk and Milk Replacers

White pan bread was long made with about 3–4% nonfat dry milk (NFDM) in the United States, for reasons of enhanced nutrition, increased dough absorption, improved crust color, fermentation buffering, and better flavor. For some years, however, sharply increased milk prices have led to a decline in its use in breadmaking. Many bakers have turned to the use of milk replacers to control the costs of their products, and these ingredients are now commonly utilized. Milk replacers were designed to duplicate some of the functions and nutrition of milk. These blends may contain soy flour or cereals, with whey, buttermilk solids, sodium or calcium caseinate, or NFDM. Milk replacers or NFDM used in bread dough amount to about 1–2%, based on flour.

NFDM and whey constitute the most important dairy ingredients, but whole dry milk, fluid milk, condensed or evaporated milks, buttermilk, and cream cheese are employed to lesser extents in the production of specialty bakery items. For use in yeast-leavened products, milk must first be specially heat treated to inactivate some unknown factor or factors that would otherwise adversely affect dough handling properties and cause the production of poor bread quality. Milk is used in many cakes, where it is quite functional in terms of stabilizing the batter and improving structure of the baked cake; it is generally more difficult to replace the functions of milk in cakemaking than it is in breadmaking. See also **Milk And Milk Products**.

Eggs

Eggs are not used much in breadmaking, except for specialty egg breads. Egg whites are occasionally used on the surface of hard rolls to impart a crispy crust. Yeast-leavened sweet doughs or danish doughs often contain egg, up to 20%, based on flour, to achieve richness and to influence color and flavor. Some bakery foods, eg, sweet goods, croissants, and puff pastry, are often washed with egg wash (a mixture of egg and water or milk) prior to baking to obtain a rich, golden brown color in the finished product.

Eggs are employed in most cakes, at levels of 35–100%, based on flour, where they are functionally important. Unique properties of whippability, heat coagulation, and emulsification are critical factors in many bakery foods. Films of proteins surrounding gas bubbles in batter, provided by egg, are important in the leavening process and ultimately to the cellular structure of the finished cake. Egg whites are used to make white and angel food cakes; for other cakes, and for sweet yeast-raised goods, whole eggs, whole eggs fortified with yolks, or occasionally yolks alone, are used.

Bakers may use egg products in liquid, dried, or frozen forms. Liquid eggs, which have been churned, filtered, and pasteurized by the egg producer, are available in refrigerated tank cars to the large wholesale bakeries. The quality of dried egg products have been immensely improved in recent years, and many types of dried eggs are widely used by U.S. bakers in their production of bakery foods. Frozen egg products have lost ground to dried eggs because the former require careful thawing, a tedious, labor-intensive, and sometimes uncertain process.

Salt

Virtually all bakery foods contain salt (sodium chloride), except for a small number of products made for individuals on low sodium diets. Salt is quite functional in yeast-leavened bakery products. In breadmaking, salt, used at roughly 2% based on flour, provides flavor, moderates yeast fermentation by increasing the osmotic pressure in dough, and toughens gluten proteins. Crystal size and solubility are important quality factors in salt. Many bakery foods are best made with fine-flaked salt that dissolves readily; on the other hand, pretzels, and some hard rolls and bread sticks, require salt crystals of a larger size as a topping for purposes of appearance and

flavor. For long shelf life foods such as crackers, it is important to use salt that is refined to minimize trace levels of iron and copper, since these tend to promote fat oxidation.

Water

The components of yeast-raised doughs and chemically leavened batters are dispersed in water. Water for dough mixing is generally not softened because the minerals in hard water may be beneficial, tending to strengthen gluten proteins. Sulfide waters have a deleterious action because the gluten protein is weakened by the sulfhydryl groups. Alkaline water, especially well-buffered alkaline water, also adversely affects bread quality since it interferes with the normal acidity development in dough, a necessary factor for flavor and overall bread quality.

Enzymes

Adequate amylolytic enzymes must be present in dough for several reasons. They break down available starch into fermentable sugars that constitute the energy source for yeast and degrade some of the starch to simpler structures during the early stages of gelatinization in baking to improve volume, texture, and keeping properties. Most wheats harvested in the United States are deficient in alpha-amylase, and flours milled from these wheats may be supplemented with enzymatic preparations. This is most typically done with the addition of malted barley flour. Fungal amylase preparations derived from *Aspergillus oryzae* are also permitted by the U.S. standards of identity for use in flour or bread, but fungal amylases are more often added at the bakery rather than the mill level. The amylase from *B. subtilis*, which is relatively heat stable and partly survives the baking process for further starch modifications, is utilized by some wholesale bakers to slow down the firming of bread. See also **Enzyme**.

Proteolytic enzymes, also derived from *A. oryzae*, may be used in yeast-raised dough production to reduce mixing time of dough or to make doughs more pliable. These functional effects are achieved through selective hydrolysis of gluten protein bonds, thus modifying dough and causing it to be more extensible.

Mold Inhibitors (Antimycotics)

Antimycotics play an important role in extending the shelf life of many bakery foods. Calcium propionate [CAS: 4075-81-4] is the most widely used antimycotic in breadmaking. It is often utilized at about 0.2%, flour basis; higher concentrations lead to flavor problems and begin to inhibit yeast fermentation. Sodium propionate [137-40-6] and potassium sorbate [CAS: 590-00-1] are used to inhibit mold growth in chemically leavened products. Potassium sorbate suspensions may be used to spray the surface of yeast-leavened bakery foods for antimycotic protection; the sorbates cannot be used in doughs because of a strong yeast-inhibiting effect. Other agents sometimes used to control microbiological growth in bakery foods include vinegar, sodium diacetate [CAS: 126-96-5], monocalcium phosphate monohydrate [CAS: 10031-30-8], and lactic acid. Proprietary materials based on the fermentation of whey are also now available for antimycotic purposes; such materials are apparently effective on the basis of propionic acid that is formed during fermentation of the whey. See also **Yeasts and Molds**.

Flavorings

Various spices are employed to provide distinctive flavors in many bakery foods. Similarly, flavors and colors, both natural and artificial, are used to enhance bakery products in terms of both eating properties and appearance. Cocoa, chocolate, and many varieties of fruit, as well as some vegetables, (fresh, frozen, canned, and dried) are used in the food product or in fillings or icings. See also **Flavors and Essences**; and **Spices**.

Enriching Ingredients

Most commercially produced white breads are enriched with added thiamin, riboflavin, and iron. When breads or rolls are labeled enriched, these nutrients must be present in amounts prescribed by federal standards of identity. In g/kg product these are thiamin 4.0, riboflavin 2.4, niacin 33, and iron 27.5. Calcium may optionally be added at 1.3 g/kg. Although federal regulations relate to interstate commerce, most states also require enrichment of white bread and rolls. Enrichment nutrients may be added by the baker to the dough in the form of tablets, as a mixture of powdered nutrients in water-soluble pouches, or as a proprietary salt-enrichment blend. Alternatively, many bakers prefer to purchase flour that has been enriched to prescribed levels during the flour milling operation. Products labeled as enriched must also carry a nutritional label. Typically, a serving of one slice, approximately 1 oz (28 g), of enriched bread provides the following percentages of the U.S. Recommended Daily Allowance: thiamin 8.0%, riboflavin 4.0%, niacin 6.0%, iron 4.0%, and calcium 4.0%.

Manufacturing and Equipment: Breadmaking

Principal process categories used in the manufacture of yeast-raised products include the sponge and dough method, the straight dough method, and highly accelerated short-time methods that include frozen dough processing, continuous mix, and liquid ferment processes. Considerable variation exists among commercial bakeries within each of these categories. Rolls, buns, and sweet yeast-raised products are produced in ways analogous to those described for bread production. Principal differences are that special makeup machinery is required to produce the various shapes, and finishing equipment is required to fill and ice sweet roll and coffee cake units.

Sponge and Dough System: Conventional Breadmaking. Most domestically produced bread is manufactured by the two-mixing stage sponge and dough process (Fig. 1).

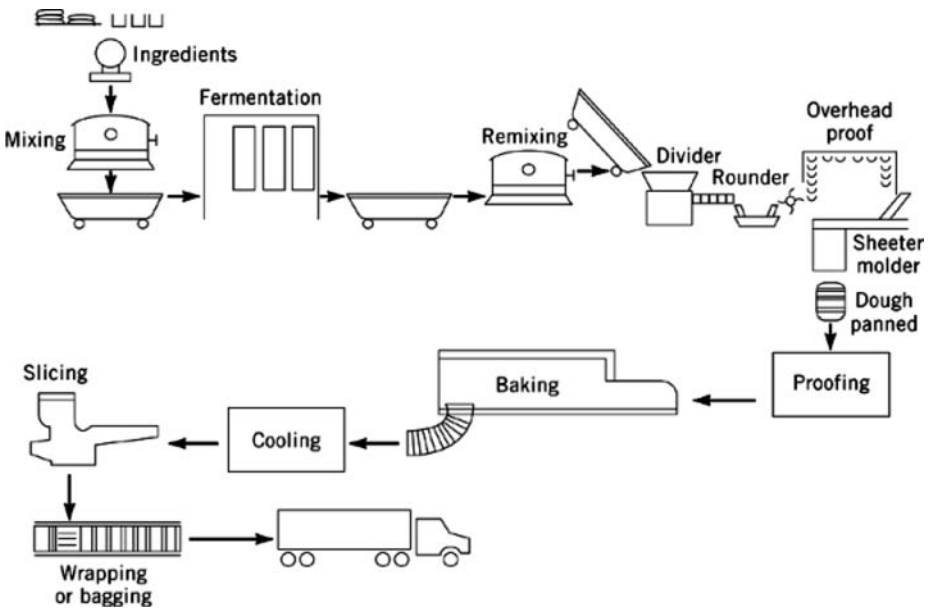

Fig. 1. Conventional dough process. (Courtesy of Union Machinery Division. American Machine & Foundry Co.)

Mixing and Fermentation of the Sponge. Sifted flour is pneumatically conveyed to a weighing hopper (scale) above a horizontal mixer. About 60–80% of the total flour required for a batch is used in mixing the sponge. Yeast, the yeast food, and the enrichment ingredients, usually presuspended in water slurries, are metered on top of the flour. The proper amount of water is metered into the bowl, and these ingredients are mixed into a sponge. The sponge may also include enzymes used as flour supplements and a fraction of the formula salt. Mixing of the sponge is intended to produce a homogeneous mass, but is not intended to produce full mechanical development of the wheat gluten. The sponge is dumped from the mixer into greased troughs which are transferred to a fermentation room. The fermentation room provides an optimum environment for sponge bulk fermentation of about 27 °C (81 °F) and 75–80% relative humidity. In practice, sponge fermentation time ranges from 2.5 to 6.0 hours, with best results usually found using 3.5–4.5 hours. As fermentation proceeds, the sponge volume increases dramatically until it reaches such extension that it drops spontaneously. This drop point is used as a reference indicating completion of 66–70% of total sponge fermentation. This bulk fermentation not only generates gas, but also generates fermentation by-products that contribute to final product flavor, develops the viscoelastic properties of dough that improve its gas retention capabilities, and reduces pH to a range that is optimum for final breadbaking results.

After the sponge has fermented sufficiently, it is returned to the mixer. The remaining flour and water, plus sugar, salt, shortening, nonfat dry milk (or milk replacer), and any other minor ingredients are added to the sponge and the final dough is mixed. Dough stage mixing is intended both to produce a homogeneous mass and also to mechanically develop the hydrated wheat gluten by repeated stretching and folding. This mixing to full development improves loaf volume, grain, and texture of the resultant loaf. There is a definite optimum mixing time range; deviation too far off the optimum in either direction harms end product quality. Mixers are jacketed so that temperatures of sponges and doughs may be partially controlled either by circulating refrigerant or brine in the jacket, or using direct-expansion coils. The properly developed dough, with a temperature of about 27 °C (81 °F), is ejected from the mixer into a greased trough where it is permitted a rest period (floor time) of 15–45 min before makeup.

Makeup. Following the floor time, the trough is hoisted and dumped to transfer the dough to the hopper of a divider. Several types of dividers are used, depending on dough consistency at this processing stage. A common type consists of pistons of adjustable size and/or "throw" which operate in cylinders. Piston movement draws dough into a cylinder, the cylinder door closes to cut off the piece of dough, and the cut dough piece is forced out of the chamber onto a conveyor belt. Ejected pieces are checkweighed frequently, and the size of the piston throw is adjusted accordingly.

The conveyor belt moves the rough, ragged dough pieces to a rounder, where they are converted to smooth, spherical shapes with consequent further mechanical development of the gluten network from the stretching and folding encountered. The rounder consists of a large rotating cone and a pressure board. Dough pieces are rolled and compressed as they are forced to travel up the pressure board by the rotating cone. Rounded dough pieces are transferred to an overhead or intermediate proofer, which is a large enclosed chamber through which the dough pieces are carried on trays suspended on a chain drive. The trip through the overhead proofer takes 7–15 min. The gluten network, which was tightened by the previous mechanical manipulation, relaxes during this period so that the dough pieces become pliable enough to successfully undergo sheeting and molding.

Dough pieces are conveyed out of the overhead proofer to a molder, usually of the cross-grain variety. In the molder, a series of reduction rollers sheet the relaxed ball-shaped dough pieces to thin flattened ovals. The resulting sheets pass through a chain curler to be formed into loosely formed cylinders. Each cylinder is tightened by passage under a compression plate. Cross-grain molders sheet each dough unit in two axes at right angles to each other, creating mechanically elongated and strengthened air cells that culminate in improved interior grain of the final baked bread loaves. At the end of the molder, these dough cylinders are automatically deposited into baking pans that are joined together in straps of four to six by means of cross pieces. Strapping facilitates handling and alignment through the next stages in the process.

Proofing. The panned dough cylinders are allowed to rise a final time in a controlled environment proof room or proofer at 35–43 °C (95–109 °F), 85–95% relative humidity. Proofing is usually designed to take about one hour. During this period, the dough piece expands to approximately six times its original volume. Proofing may be accomplished by continuously conveying the pans through a proofer or alternatively, pans may be manually loaded onto racks which are transferred into a proofer.

Baking. If a continuous proofer was used, pans of proofed dough are mechanically conveyed into the oven. If proofing was done on racks, strapped pans are transferred to the oven by hand. Most large-scale bakeries use traveling tunnel or lap ovens in which bread pans are loaded at one end and the baked loaves exit the other. Such ovens generally consist of several chambers at different temperatures. One pound (0.45 kg) loaves generally bake at 215–225 °C (419–437 °F) for 17–23 min, depending on formulation and desired end product. Smaller bakeries may use reel ovens, in which trays are rotated about a horizontal axis reel, or one of a number of ovens using heated air blown at high speed including convection ovens, rotating rack ovens, and air-jet impingement ovens.

Cooling, Slicing, and Wrapping. Baked bread is depanned automatically and conveyed through a cooler to lower loaf interior temperature to 40.5 °C (105 °F). Loaves are conveyed to a slicer where they are sliced by bandsaw blades. Sliced bread loaves are then bagged in plastic bags, or less frequently today, in waxed paper or transparent film. Packages are twist-tied or plastic clipped, or alternately heat sealed.

The sponge and dough process is used to manufacture a wide variety of yeast-leavened products that extend beyond the scope of the pan bread manufacturing process discussed here. To illustrate, sweet roll doughs often utilize the sponge and dough process. Such sweet doughs are characterized by their richer formulas, the equipment used to create their specific shapes, and equipment used to fill, ice, and package these products.

Straight Dough Method

The straight dough method differs from the sponge and dough method in that all ingredients are mixed in a single mixing stage to full development. Following mixing, the dough undergoes a bulk fermentation period of about two hours at 27 °C (81 °F). Fermentation is followed by a "punch" in which the risen dough is folded over on itself in its trough. The punch deflates the dough, expelling excess carbon dioxide gas and contributing to the strength (elasticity) of the maturing dough via the mechanical manipulation of the gluten network. A floor time of about 30 min follows, after which the dough is divided into desired unit pieces, rounded and rested briefly, then molded into loaves or other desired shapes. Subsequent processing is identical to that described in the sponge and dough method. Domestically, the straight dough method is used primarily in smaller retail-scale bakeries. It is sometimes used in larger commercial bakeries for short production runs of specialty products. In general, straight dough processes are more sensitive (less tolerant) to deviations in the processing steps than sponge and dough versions utilizing the same formula.

A variation on the straight dough method is the category of remixed straight doughs in which most or all ingredients are mixed to homogeneity, bulk fermented, then remixed to full development, given a short floor time, and subsequently processed as normal. In a sense, a remixed straight dough can also be considered a 100% flour sponge and dough system. Such methods are useful in smaller bakeries desiring maximum flexibility with respect to production scheduling.

No-Time Doughs. No-time or short-time dough processes are a special subset of the straight dough method. Increased amounts of yeast and such fast-acting oxidants as ascorbic acid and azodicarbonamide [CAS: 123-77-3] (ADA) enable the elimination of most of the normal straight dough bulk fermentation period. Though attractive from an economic and production planning viewpoint, products of these processes tend to have open grain, less flavor, and shorter shelf lives. No-time processes are used advantageously in the production of short-lived hard-crusted hearth breads in smaller bakeries, and in the larger-scale production of frozen dough products.

Frozen Dough Products. Frozen dough products have found increasing acceptance as the numbers of skilled baker/artisans available to small bakeries have declined. End users of frozen dough products are typified by the growing number of grocery store in-store bakeries.

Doughs intended for frozen dough production usually include reduced water percentages and increased amounts of water-binding ingredients to minimize the amount of free water available for ice crystallization. No-time

dough processes are generally used for frozen dough in order to minimize yeast activation prior to freezing. With minimized activation, yeast cells appear to be less damaged by the ice crystallization that occurs in frozen storage. The no-time dough process is thought to yield dough products that are least damaged by freezing and by frozen storage relative to gas production and gas retention capability. Dough strengthener additives, such as SSL and DATEM, are used to partially counter the structure weakening effect of glutathione leached from yeast cells that have been damaged during freezing. Frozen doughs that are produced from no-time doughs necessarily include high concentrations of oxidants including ascorbic acid, azodicarbonamide, and to a lesser degree, potassium bromate.

After mixing, doughs are immediately divided and rounded, rested briefly, then molded. Molded units are rapidly frozen in blast (or other) freezers until reaching a core temperature of about -7 to $-5\,^{\circ}C$ (19 to $23\,^{\circ}F$). Units are boxed and stored at $-18\,^{\circ}C$ ($-0.40\,^{\circ}F$), then shipped to end users. End users slowly thaw these products in $2\,^{\circ}C$ ($35.6\,^{\circ}F$) retarders over 16–18 h, proof, and bake the products as needed.

Continuous-Mix Breadmaking Process. Continuous breadmaking uses equipment which continuously mixes and deposits dough in pans. This manufacturing method differs markedly from the conventional sponge and dough method discussed above, and produces loaves with characteristics substantially different from the bread produced by the conventional methods. Early versions of the continuous-mix process accomplished fermentation in a liquid water brew containing water, yeast, sugar, yeast food, and enrichment nutrients. Subsequent continuous-mix methods featured the use of some percentages of the total flour (up to 70%) in the brew. Proponents of flour usage in brews claimed improvements in bread flour and overall bread quality. The fermented brew is metered into a premixer along with flour, shortening, additional sugar, a dairy ingredient, other optional ingredients, and an oxidizing agent solution of potassium bromate and azodicarbonamide (ADA, 1,1′1-azobisformamide) to form a more or less homogeneous dough. This is pumped into a continuous developer where rapidly rotating agitators mechanically develop the dough. The developed dough is extruded under pressure as a ribbon which is automatically cut into properly sized pieces. These drop into pans and are subsequently proofed and baked.

Continuous-mix bread processes are economically attractive alternatives to conventional batch breadmaking processes. Because of this it is estimated that continuous-mix plants accounted for nearly 40% of domestic white pan bread production in the late 1960s and early 1970s. However, the end product lacks the grain and bite that the market expects of its bread, as well as the subtle yet complex flavor of breads produced from doughs that have undergone bulk fermentation. Some continuous-mix bakeries, as noted above, found that improved bread flavor could be obtained by including a percentage of the formula flour in the fermenting brew, but grain remained unchanged. Consumer preference has pulled most manufacturers back to more conventional breadmaking processes, and continuous-mix bread today accounts for perhaps only 5% of domestic bread production.

Liquid Ferment Processes. The second most prevalent commercial dough making process today is the liquid ferment category, accounting for about 20% of domestic bread production and nearly all bun production. Liquid ferment processes use either a water brew, or more commonly today, a fermented flour-containing brew, or liquid sponge, in conjunction with a batch-mixing process using conventional horizontal mixers. After mixing, dough pieces are divided, rounded, rested, and molded as in the conventional breadmaking process.

The higher the percentage of flour included in the fermenting brew, the more improved is final product flavor, and the lower the oxidant addition requirements. It is possible to use as high as 70% of formula flour in a brew, but this requires all of the formula water to still have a pumpable slurry. In practice, most bakeries use flour brews that include about 40% of formula flour.

Flour brews are usually mixed and fermented in batches. Alternatively, these brews may be mixed and fermented on a continuous basis in which the flour brew, or liquid sponge, is moved progressively through a fermentator tank system. Depending on the equipment design and the consistency of the brew system used, movement through the fermentator tank is accomplished either by means of brew density changes through time or by rotors.

Other Yeast-Leavened Product Categories

Buns and Rolls. Hamburger and hot dog buns and rolls may be processed in a manner directly analogous to those used for bread production. Almost all domestically produced bun products are produced by a batch liquid ferment process. After mixing, doughs are immediately divided and rounded to small unit-sized balls. Following a brief rest, these are given their final shape, proofed, baked, cooled, and packaged.

Sweet Yeast Goods. Sweet roll and coffee cake production is likewise directly analogous to bread-production methods. Chief differences are in makeup equipment used to produce the specific shapes and sizes of units. Also, following baking and cooling, sweet goods are “finished,” ie, iced and/or filled prior to packaging.

English Muffins. English muffins are fairly tough, chewy, and honeycombed with holes and have a somewhat sour flavor. Typically made by the sponge and dough method, the final dough of English muffins has a comparatively high water content which makes the dough soft enough to flow. These soft dough units flow to fill griddle cups into which they have been deposited. Units are baked in these covered griddle cups on a highly automated line.

Bagels and Pretzels. Though their production processes are not necessarily typical of other yeast-leavened products, the principal distinguishing feature of these products is that they are both cooked briefly in a boiling water bath just before transfer to the hearth of an oven. The boiling water bath gelatinizes starch on the surface of the units, yielding a glossy crisp surface on the finished product.

Croissants and Danish. Both product categories are produced from laminated doughs. Croissant dough consists of a white bread straight dough into which butter is folded to create 27–54 layers. Similarly, Danish doughs are lean sweet roll doughs laminated with butter and/or other solid fats. In the Scandinavian countries, the weight of roll-in butter is generally about half the total weight of the dough being laminated. Following the lamination process, these doughs are retarded to facilitate subsequent sheeting and makeup. After makeup and proofing, these laminated dough units additionally puff gently upon oven heating, creating a crisp, friable, flaky, and buttery texture to the final product.

Raised Doughnuts. Mixing and fermentation of raised doughnut doughs,like that of sweet roll doughs, is virtually identical to processes used in bread manufacture and sweet roll dough production. The only significant difference is that the proofed units are fried instead of baked for approximately 1 min per side in $191\,^{\circ}C$ ($376\,^{\circ}F$) fat. Fried units are cooled and drained briefly, then glazed or finished as desired.

Crackers and Cookies

These products have long shelf lives and so may be distributed over wide geographic areas. For this reason, cracker and biscuit plants are generally larger than those producing bread and cake products. This large volume from a single plant warrants more expensive and intricate mechanical equipment, and these plants are the most highly automated in the baking industry. Their products are generally produced from soft wheat flours, usually straight grade; saltine crackers may be made with some hard wheat flour to provide strength during dough processing.

Saltine cracker manufacture begins with mixing of a sponge consisting of 65% of the formula flour (10% protein), a small amount of yeast, and 27% water, considerably less than is used in a sponge for bread production, plus a lactobacillus inoculum provided by a portion of an old dough “starter.” The sponge is fermented for 18 h. By the end of sponge fermentation, sponge pH has reached 4.0, activating the proteolytic enzymes naturally found in flour to yield greatly increased extensibility. The remaining 35% flour (8.5–9% protein), fat, salt, plus sufficient sodium bicarbonate to raise final dough pH to 7.5 are added at the dough mixing stage. This dough is allowed to ferment for 6 h. The dough is sheeted and laminated, then sheeted and scored into the shapes and sizes desired. Crackers are baked on a moving steel band in a tunnel oven.

Snack crackers are made from nonfermented straight doughs that obtain required extensibility via chemical or enzymatic means. They have harder, denser, and less friable texture than saltines, and obtain their flavor mostly from artificial flavors incorporated in the dough or sprayed onto the surface of baked crackers. Cookies are also made from a nonfermented dough. Cookie doughs contain eggs, sugar, flour, shortening, milk, salt, leavening agent, flavoring, and possibly fruits and nuts. Shapes are obtained by extrusion or by passing the sheeted dough under rollers with appropriate dies, and these are likewise baked in a band oven.

Nutritionally Modified Yeast-Leavened Products

Current growth segments in bakery foods markets include products with formula modifications that provide high fiber, reduced food calories, reduced total and saturated fats, and/or reduced cholesterol. The potential for percentage calorie reduction in bread products is somewhat limited by their relatively low fat and sugar content and their relatively low total caloric value. The need for high fiber foods in diets is today widely recognized. High fiber breads are often reduced in calories; this reduction is largely achieved through the use of various nondigestible fibers and increased water in the formula. In richer dough products, ingredients may be replaced with materials that attempt to simulate the function of fats. This substitution may be either in the dough itself, as with reduced fat sweet dough items and low fat crackers, or in the roll-in fat of laminated doughs, as with reduced fat Danish products. Some typical fat replacers include modified food starches, gums, emulsifiers, polydextrose, microparticulate protein, and β-glucan fiber. See also **Fat Replacers**. High fiber ingredients with low calorie content may be used as bulking agents to replace higher calorie ingredients (sugar, flour), but mostly these are nonfunctional "dead weight." High intensity sweeteners such as sugar substitutes will be increasingly useful as workable bulking agents are developed.

Standards of Identity for Bakery Foods

Federal standards of identity exist for white bread, enriched bread, milk bread, raisin bread, and whole wheat bread that move in interstate commerce. Many states have adopted the federal standards or have promulgated nearly identical laws. Most bakery foods sold in the United States are produced by large commercial bakeries engaged in interstate commerce. As a result, nearly all bread and rolls necessarily conform to the federal standards. The FDA has taken the position that if an ingredient or packaging material has crossed state boundaries, then products containing that ingredient or wrapped in that packaging material are covered under regulations pertaining to interstate commerce. Most specialty breads, such as rye, multigrain, pita, and French, are not covered by standards of identity. All ingredients permitted in standardized bakery foods are considered optional ingredients and therefore must be declared in ingredient legends on bread wrappers. Since 1975, the FDA has required that all enriched bread-type products bear nutrition labeling.

BALANCE. 1. (Chemistry) Exact equality of the number of atoms of various elements entering into a chemical reaction and the number of atoms of those elements in the reaction products. For example, in the reaction $NaOH + HCl \rightarrow NaCl + H_2O$, the atoms in the input side are H[2], Na[1], O[1], and CI[1]. Each of these is also present in the products, though in different combination. The atoms of catalysts (when present) do not enter into reactions and therefore are not involved. The balance of chemical reactions follows the law of conservation of mass. The term *material balance* is used by chemical engineers in designing processing equipment. It denotes a precise list of all the substances to be introduced into a reaction and all those that will leave it in a given time, the two sums being equal.

2. A precision instrument designed for weighing extremely small amounts of material with high accuracy. An analytical balance or microbalance for weights from about 1 g to 0.1 mg is standard equipment in chemical laboratories. Its essential feature is a one-piece metal beam (lever) pivoted on a knife-edge or flexure at its exact center (fulcrum) so that it is free to oscillate. From it are suspended two scale pans approximately 2 inches in diameter, each of which is also positioned on a knife-edge on the lower arms of the beam. Exact balance is indicated by a pointer attached to the beam. Either an aluminum rider or a chain and vernier is provided for maximum accuracy. Highly sophisticated balances operating electronically with built-in microprocessors have become available in recent years. See also **Balance (Mechanical)**.

BALANCE COIL. A balance coil is a coil for supplying a three-wire circuit from a two-wire circuit. A 240-volt single-phase line, for example, can be used to supply two 120-volt circuits consisting of three wires, one of which is a common intermediate wire. The voltage between the intermediate wire and either of the outside ones is 120 volts. If the loads on the two 120-volt circuits are unequal, the voltage can be balanced by an adjustment of the central tap point at the balance coil. A balance coil is frequently an auto-transformer having only one coil, a certain portion of which is used for both a high and low tension winding. The auto-transformer has connections at the ends of the coil, and an intermediate connection. See Fig. 1.

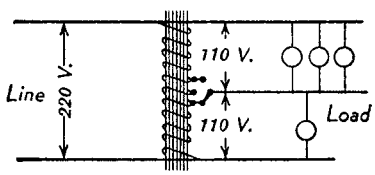

Fig. 1. Balance coil for alternating current.

In D.C. circuits the balance coil is used in conjunction with the generator to obtain a three-wire system. The generator windings are tapped at two diametrically opposite points and these taps are connected to the ends of a balance coil. The third wire for the system is obtained by connection to the center of the balance coil.

BALANCED DETECTOR. 1. Demodulator for frequency-modulation systems. In one form the output consists of the rectified difference of

the two voltages produced across two resonant circuits, one circuit being tuned slightly above the carrier frequency and the other slightly below. 2. A detector for bridge or other null circuits, which include a balanced amplifier.

BALANCED LINE. A two-conductor balanced line is a transmission line consisting of two conductors, in the presence of ground, capable of being operated in such a way that when the voltages of the two conductors at all transverse planes are equal in magnitude and opposite in polarity with respect to ground, the currents in the two conductors are equal in magnitude and opposite in direction. Currents flowing in the two conductors of a balanced line which, at every point along the line, are equal in magnitude and opposite in direction, are called balanced currents. Similarly, voltages (relative to ground) on the two conductors that are equal in magnitude and opposite in direction at every point along the line, are called balanced voltages.

BALANCED MODULATOR. A balanced modulator circuit is used to generate the sidebands of an amplitude modulated wave (see **Modulation**) and suppress the carrier. Since the power involved in a modulated wave is distributed at 100% modulation such that the carrier frequency component has $\frac{2}{3}$ and each sideband $\frac{1}{6}$ of the total, suppression of the carrier eliminates the necessity of supplying a major portion of the power usually needed. The output of such a modulator could be transmitted as only the sidebands, but in order to demodulate it a carrier wave would have to be introduced at the receiver. Such a system is known as a double sideband and suppressed carrier system. It is not used in practice because the carrier introduced at the receiver must have almost exactly the frequency of the one removed at the transmitter. Technical difficulties make this impractical. The balanced modulator output is normally fed through a filter circuit that cuts out one sideband, and the other is transmitted. This gives single sideband, suppressed carrier transmission and is widely used, especially in telephony, since the frequency requirements for the carrier introduced at the receiver are not nearly so strict as the previous case. The reintroduced carrier needs to have an amplitude comparable to the received signal which is, of course, a small part of that needed at the transmitter of a radio system. The frequency band occupied by a single sideband, suppressed carrier system is somewhat less than half that needed for a full system. This is an important asset in telephone carrier circuits where the transmission line characteristics limit the total frequency band that can be transmitted. The single sideband system allows twice as many channels as on a given line.

BALANCED OSCILLATOR. An oscillator in which the impedance centers of the tank circuits are at ground potential, and the voltages between either end and their centers are equal in magnitude and opposite in phase.

BALANCE EQUATION. In general, an equation expressing a balance of quantities in the sense that the local or individual rates of change are zero. More specifically, it is a diagnostic equation expressing a balance between the pressure field and the horizontal field of motion:

$$f\nabla_{\mathrm{H}}^2\psi + \nabla_{\mathrm{H}}\psi \cdot \nabla_{\mathrm{H}} f + 2(\psi_{xx}\psi_{yy} - \psi_{xy}^2) = g\nabla_{\mathrm{H}}^2 z$$

where ψ is the stream function for the nondivergent portion of the motion, f the Coriolis parameter, ∇_{H} the horizontal del operator in the isobaric surface, ∇_{H}^2 the corresponding Laplacian operator, g the acceleration of gravity, z the elevation of the isobaric surface, and subscripts denote partial differentiation. The balance equation is derived from the divergence equation on the assumption that the magnitude of the horizontal divergence is always much less than that of the (vertical) vorticity, and is therefore more general than the equation of geostrophic equilibrium to which it reduces in the absence of the nonlinear terms. In the case of circular contours, this nonlinear correction is the same as that introduced by the gradient wind assumption.

BALANCE (Mechanical). The equilibrium of masses is a definition for *mechanical balance*. Static balance should be differentiated from dynamic balance. Static balance occurs in a system when the center of gravity of the system coincides with its reactions. For example, a rotating body in static balance has its center of gravity coincident with its axis of rotation. A system may, however, be in static balance, but become unbalanced when the system rotates. Such a system, for example, as that shown in Fig. 1 may well be in static balance, and satisfactorily pass a balance test which would consist of putting the shaft on absolutely horizontal parallel rails and trying the rotor for equilibrium in any position. But when this system rotates, the centrifugal forces of the two weights, not being in the same plane perpendicular to the axis of rotation, create a couple acting on the shaft. That couple rotates with the shaft and produces shaking forces at the journals, and vibrations in the foundation. The dynamic balancing of this system would involve the addition of a system of counterbalances which, by themselves, would be in static equilibrium, but which in rotation would produce a couple equal in magnitude but opposite in direction to the one already considered.

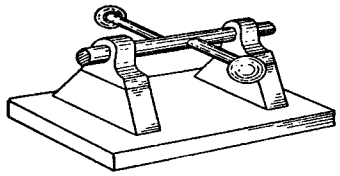

Fig. 1. Case of static balance and dynamic unbalance.

Dynamic balance is especially important in high-speed or heavy rotating machinery, as the vibrating forces are proportional to the mass and the square of the speed of rotation. Manufacturers frequently use balancing machines for testing their product when it is especially important that it be perfectly balanced.

Reciprocating balance consists of opposing the shaking forces of a reciprocating mass by equal and opposite forces obtained from another reciprocating mass. One particularly difficult job of balancing occurs in a system consisting of both rotation and reciprocation, as exemplified by the piston, connecting rod, and crank mechanism. The difficulty lies in the fact that if perfect balance is secured in the direction of reciprocation by the employment of rotating counterbalances, severe unbalance will result in a plane perpendicular to that direction. The solution of this difficulty is a compromise in which only part of the reciprocating mass is counterbalanced, thus reducing the maximum degree of unbalance, but producing a smaller unbalance in two planes.

BALANCER SET. This consists of two shunt dynamos connected in series across a two-wire D.C. distribution system to supply the third wire for a three-wire system. Either machine may act as motor or generator, the action being determined by the direction of unbalance of the load. For unbalanced loads one machine motors and drives the other as a generator to tend to restore the voltage balance.

BALANCE SCALES. See **Scale**; and **Weighing**.

BALANCE (Weighing). See **Weighing**.

BALANCING (Mechanics). A principle of statistical mechanics that shows that the steady state of affairs at equilibrium is maintained by a direct balance between the instantaneous rates of opposing processes. Thus, at equilibrium, the number of processes that destroys a situation A and produces a situation B is equal to the number of processes that destroys B and produces A. This principle is often valid, but not always; in the presence of a magnetic field, for instance, it does not hold for all processes A and B. It was called by Tolman the principle of *microscopic reversibility* and plays an important role in the derivation of the Onsager relations.

BALANOGLOSSUS. A genus of worm-like marine animals belonging to the lower chordates. The name is also commonly applied to any of the similar animals of several genera.

BALANTIDIASIS *(Balantidiosis, Balantidial Dysentery).* Balantidiasis is an intestinal disease seen almost worldwide. Balantidiasis is caused by the large ciliated protozoan, *Balantidium coli*. The organism is usually found in the lumen of the large intestine of humans and animals. Cysts formed in the lumen of the colon or in freshly evacuated feces of humans or domesticated and wild animals, can colonize the colon and terminal ileum of new hosts by the latter's ingestion of contaminated food or water. The hog has been found to be the most heavily parasitized host. Its association with the rat may be a means for maintaining a reservoir infection in the two animals.

Balantidiasis is transmitted primarily by eating food or drinking water that has been contaminated by human or animal feces containing *B. coli* cysts (Fig. 1). During its life cycle, this organism exists in two very different forms: the infective cyst or capsuled form, which cannot move but can survive outside the human body because of its thick, protective covering; and the disease-producing form, the trophozoite, which although capable of moving, cannot survive once excreted in the feces and, therefore, cannot infect others. In the digestive tract, the cysts are transported to the intestine where the walls of the cysts are broken open by digestive secretions, releasing the mobile trophozoites. Once released within the intestine, the trophozoites multiply by feeding on intestinal bacteria or by invading the lining of the large intestine. Within the lining of the large intestine, the trophozoites secrete a substance that destroys intestinal tissue and creates sores (ulcers) or abscesses. Trophozoites eventually form new cysts that are carried through the digestive tract and excreted in the feces. Under favorable temperature and humidity conditions, the cysts can survive in soil or water for weeks to months, ready to begin the cycle again.

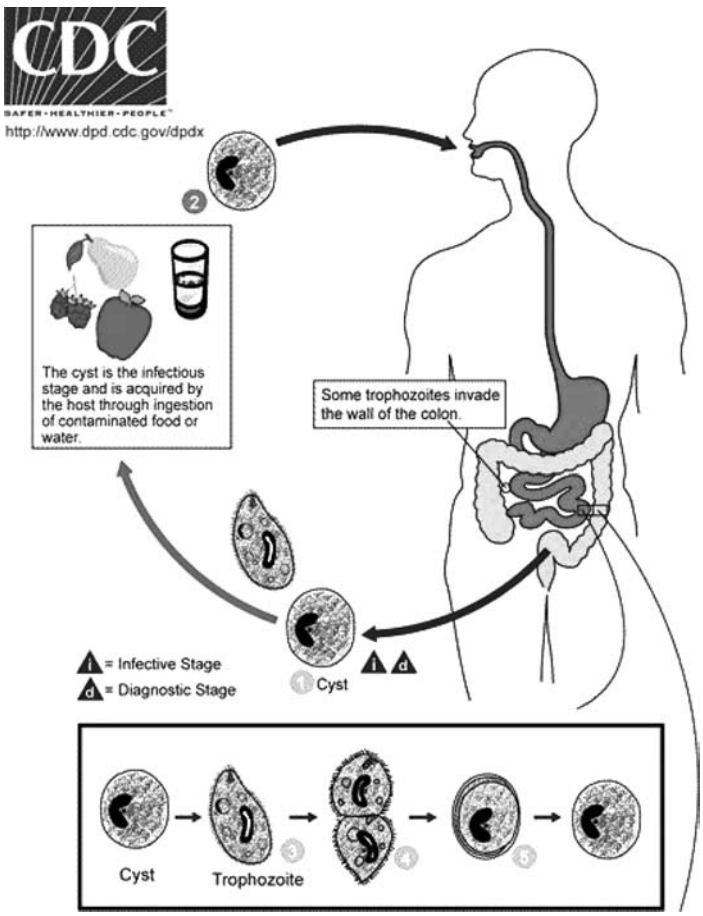

Fig. 1. Life Cycle of *Balantidium coli*. Cysts are the parasite stage responsible for transmission of balantidiasis 1. The host most often acquires the cyst through ingestion of contaminated food or water 2. Following ingestion, excystation occurs in the small intestine, and the trophozoites colonize the large intestine 3. The trophozoites reside in the lumen of the large intestine of humans and animals, where they replicate by binary fission, during which conjugation may occur 4. Trophozoites undergo encystation to produce infective cysts 5. Some trophozoites invade the wall of the colon and multiply. Some return to lumen and disintegrate. Mature cysts are passed with feces 1.

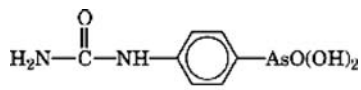
Most individuals with balantidiasis have no noticeable symptoms. Even though these individuals may not feel ill, they are still capable of infecting others by person-to-person contact or by contaminating food or water with cysts that others may ingest, for example, by preparing food with unwashed hands. The most common symptoms of balantidiasis are chronic diarrhea or severe colitis with abdominal cramps, pain, and bloody stools. Complications may include intestinal perforation in which the intestinal wall becomes torn, but the organisms do not spread to other parts of the body in the blood stream.

Diagnosis of balantidiasis, as with other similar diseases, can be complicated, partly because symptoms may or may not be present. A diagnosis of balantidiasis may be considered when a patient has diarrhea combined with a possible history of recent exposure to amebiasis through travel, contact with infected persons, or anal intercourse. See also **Amebiasis (Amebic Dysentery)**.

Specifically, a diagnosis of balantidiasis is made by finding *B. coli* cysts or trophozoites in the patient's stools or by finding trophozoites in tissue samples (biopsy) taken from the large bowel. A diagnostic blood test has not yet been developed.

Patients with balantidiasis are treated with prescription medication, typically consisting of a ten day course of either tetracycline [CAS: 60-54-8], oxytetracycline [CAS: 79-57-2], or chlorotetracycline [CAS: 57-62-5]. Metronidazole [CAS: 443-48-1] and iodoquinol [CAS: 83-73-8] are also effective. Alternative drugs that have proven effective in treating balantidiasis include paromomycin [CAS: 59-04-1], tinidazole [CAS: 19387-91-8], sulfadiazine [CAS: 68-35-9], and carbarsone [CAS: 121-59-4] (1, *p*-ureidobenzenearsonic acid, $C_7H_9AsN_2O_4$, Ameban).



(31)

There are no immunization procedures or medications that can be taken prior to potential exposure to prevent balantidiasis. Moreover, people who have had the disease can become reinfected. Prevention requires effective personal and community hygiene. Specific safeguards include the following:

- Purification of drinking water. Water can be purified by filtering, boiling, or treatment with iodine.
- Proper food handling. Measures include protecting food from contamination by flies, cooking food properly, washing one's hands after using the bathroom and before cooking or eating, and avoiding foods that cannot be cooked or peeled when traveling in countries with high rates of balantidiasis.
- Careful disposal of human feces.
- Monitoring the contacts of balantidiasis patients. The stools of family members and sexual partners of infected persons should be tested for the presence of cysts or trophozoites.

BALD EAGLE. See **Eagle**.

BALLAST. Any material used for the purpose of providing stability is called ballast. Ballast is used in ships to bring the center of gravity of the vessel below a point called the metacenter, when there is a lack of cargo that would produce the same effect. Balloons and airships carry ballast, which acts as a stabilizer and provides a means of controlling the rate of gain of rise as well as the altitude. Light vehicles that move at high speeds are often provided with ballast to lower the center of gravity and prevent overturning. Sand or water are very useful for ballast. Crushed stone placed under and between railroad ties to absorb impact and provide smooth riding conditions is also called ballast.

In an electrical lighting system, a ballast is a device used with an electric-discharge lamp to obtain the required circuit conditions, such as voltage, current, and wave form, for starting and operating.

BALLISTIC BODY. A body free to move, behave, and be modified in appearance, contour, or texture by ambient conditions, substances, or forces, as by the pressure of gases in a gun, by rifling in a barrel, by

gravity, by temperature, or by air particles. A rocket with a self-contained propulsion unit is not considered a ballistic body during the period of its guidance or propulsion.

BALLISTIC CAMERA. A ground-based camera using multiple exposures on the same plate to record the trajectory of a rocket.

BALLISTIC CONDITION. A condition affecting the behavior of a vehicle in flight. Ballistic conditions include the velocity, weight, shape, and size of the vehicle; likewise the density and temperature of the ambient element, the magnetic field, etc.

BALLISTIC DENSITY. A representation of the atmospheric density actually encountered by a projectile in flight, expressed as a percentage of the density according to the standard artillery atmosphere.

Thus, if the actual density distribution produced the same effect upon a projectile as the standard density distribution, the ballistic density would be 100%.

BALLISTIC MEASUREMENT. Any measurement in which an impulse is applied to the measuring device and the subsequent motion of the device is determined as a measure of the impulse. See **Ballistic Pendulum**; and **Galvanometer**.

BALLISTIC MISSILE. A missile designed to operate primarily in accordance with the laws of ballistics. A ballistic missile is guided during a portion of its flight, usually the upward portion, and is under no thrust from its propelling system during the latter portion of its flight; it describes a trajectory similar to that of an artillery shell.

BALLISTIC PENDULUM. An instrument used for measuring the horizontal velocity component of a projectile. In its usual form it consists of a simple pendulum of mass M, and of natural frequency f. A projectile of mass m, moving with a velocity V strikes the bob and is imbedded in it. The maximum excursion X of the bob is then measured. Assuming that $M \gg m$ and that little damping is present, it may be shown by application of conservation laws that

$$V = \frac{2\pi f X M}{m}$$

BALLISTICS. Ballistics is the science that treats the motion of masses projected into space, especially as associated with the motion of projectiles from guns, and certain aspects of the motion of rockets. The subject of ballistics is conventionally divided into three parts: interior ballistics, exterior ballistics, and terminal ballistics.

Interior ballistics is largely interwoven with the study of thermodynamics — the pressure, volume, and temperature of an expanding gas during travel of the projectile in the bore. It is concerned with the amount and combustion characteristics of gunpowder. The maximum pressures, and location of the same, stresses in the barrel, and the design of the barrel to resist these stresses may also be said to be interior ballistics.

Exterior ballistics deals with the motion of the projectile after it has left the gun. The science of exterior ballistics might be said to have been rationally developed by Newton as a byproduct of his study in gravitation. If the effect of air on the motion of a projectile is omitted, then the trajectory is parabolic, since as soon as the bullet or shell leaves the muzzle of the gun, force of gravity begins to pull it toward the earth. It is therefore impossible for a bullet to travel in a straight line, and if it is to return to a target at the same elevation as the muzzle, it must have an initial upward component given by aiming the barrel somewhat above the target. If the muzzle velocity is V, and the inclination of the barrel to the horizon is i, its upward component is $V \sin i$. If the action of gravity is wholly unresisted, the time it will take to reach the top of trajectory (at which point the upward component has been reduced to zero) is the same as that required by a freely falling body to attain a velocity equal to that of the vertical component at the muzzle. Assuming a simple case where the target is at the same level above the earth's surface as the gun, it would take another equal interval of time for the projectile to move from the top of its trajectory to the target. The distance to the target would be that covered by the horizontal component $V \cos i$ in the period of time taken by the projectile in reaching the top of its trajectory, and then returning to its original level.

But the effect of air forces cannot be neglected, practically speaking, and the simple equations derived from the mechanics of a freely falling body are not applicable without considerable modification. The retarding effect of air and the effect of winds must be included, as must the spin of the projectile and its behavior under the action of these forces, as a gyroscope.

The methods of exterior ballistics are also useful in all design of rockets, where they must be considered in combination with the self-contained propulsion and control systems. This is particularly true of the (low-level) sounding rockets and ballistic missiles in which the controls shut off the propulsion system when a preset velocity and azimuth has been attained. From then on, the trajectory of the missile is determinable entirely by methods of exterior ballistics.

Terminal ballistics is concerned with fragmentation, blast, and penetration of armor and concrete.

BALLISTIC TEMPERATURE. That temperature (in °F) which, when regarded as a surface temperature and used in conjunction with the lapse rate of the standard artillery atmosphere, would produce the same effect on a projectile as the actual temperature distribution encountered by the projectile in flight.

BALLISTIC TRAJECTORY. The trajectory followed by a body being acted upon only be gravitational forces and the resistance of the medium through which it passes. A rocket without lifting surfaces is in a ballistic trajectory after its engines cease operating.

BALL LIGHTNING. A relatively rare form of lightning, consisting of a reddish, luminous ball, of the order of 1 foot in diameter, which may move rapidly along solid objects or remain floating in midair. Hissing noises emanate from such balls and they sometimes explode noisily, but may also disappear noiselessly. Also called *globe lightning*. It has been suggested that ball lightning is a temporarily stable plasma. See **Lightning**.

BALLON CEILING. See **Meteorology**.

BALLOON. A non-rigid, lighter-than-air craft, receiving its sustention from the buoyancy of the gas it contains. The shape, usually spherical, is formed by the internal pressure of the lifting gas. The lifting medium first used was air, which was expanded and made lighter than the atmosphere by heat; this hot-air balloon was devised by the Montgolfiers in 1783. See Fig. 1. Coal gas and hydrogen were other early lifting media. Paper, oiled silk, goldbeater's skin, and rubber were among the materials from which the first balloons were made. Scientific balloons currently are made of plastic materials.

The hydrogen-filled balloon shown here was manned by the physicist Jacques Charles and an assistant, M. Robert. The first part of the flight lasted about two hours, after which Robert disembarked. Charles then continued the flight, ascending to an altitude of about two miles (3 km). Possibly the most interesting aspect of this flight from a scientific standpoint was the fact that a scientist engineered the flight and was aboard.

The 1780s were notable for the development and testing of the balloon. Competition for flight records was exciting for the balloonists and the populace alike. On January 10, 1784, Joseph Montgolfier made an impressive flight in a hot-air balloon (straw-fired) named *Flesselles*. The balloon was 180 feet (55 meters) high and measured approximately 100 feet (30 meters) around. In the comparatively short period of 17 minutes, the balloon reached a height of 3000 feet (914 meters), while carrying seven passengers. In August 1784, the French chemist, Guyton de Moreau, accompanied by one attendant, reached a height of about 10,000 feet (3050 meters) and collected atmospheric temperature and pressure data. The first crossing of the English Channel (Dover-Calais) was achieved in January 1785 by the French aeronaut Jean Pierre Blanchard and an American physician, John Jeffries.

Classes

Balloons may be (1) *captive*, secured by a cable to the ground, such as those used for military observation and communication purposes or as protective means used against enemy bombers, or (2) free, floating through the atmosphere untethered to the ground. In terms of practical applications, captive balloons sometimes are used as "attention getters." Free balloons are used for numerous scientific purposes and by sportsmen,

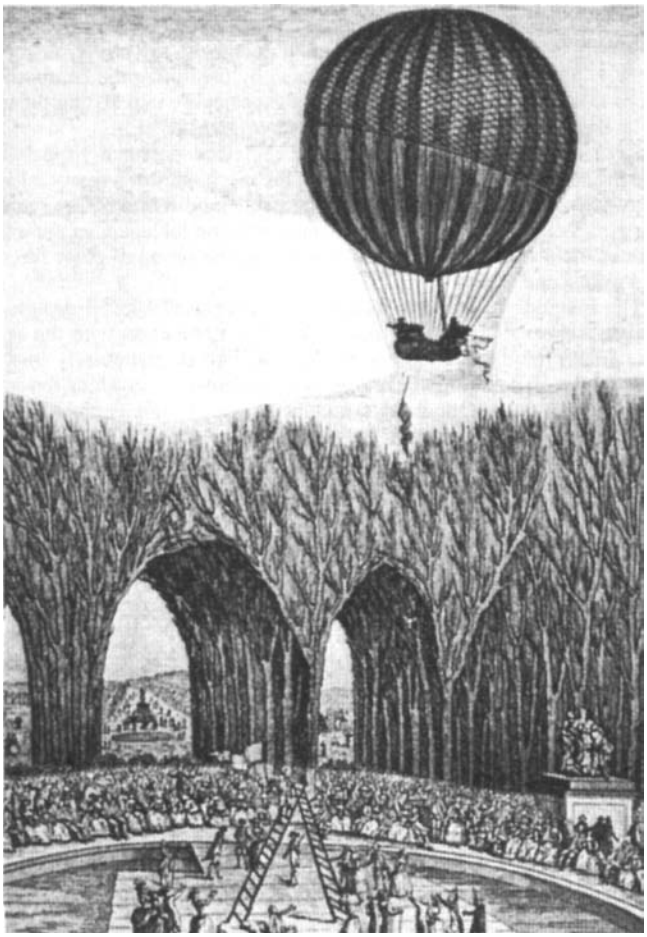

Fig. 1. Early depiction of the first free flight of a manned hydrogen balloon just after it was launched from the Tuileries Gardens, Paris, France on December 1, 1783. This occurred just a few days after the first manned hot-air balloon, designed by the Montgolfier brothers, was launched over Paris (November 21, 1783). Six months earlier (June 4, 1783), the Montgolfier brothers launched a non-manned hot-air balloon for a ten-minute demonstration flight.

serious adventurists who are seeking new records for balloon performance, and, in more recent years, as a basis for balloon trips by tourists.

Early History of Ballooning

The late Prof. Arthur F. Scott (Reed College) in an interesting paper published posthumously [edited from original papers by Joel Keizer (University of California, Davis)] studiously connects the early interest in balloons to chemistry. The article, "The Invention of the Balloon and the Birth of Modern Chemistry," *Sci. Amer.*, 126–137 (January 1984) is suggested reading. As observed by Scott, "The flight [Montgolfier, 1783] was remarkable in its own right, but it also epitomized a major achievement in chemistry, namely the fall of the phlogiston theory of chemical composition under the impact of the discovery that gases are distinguishable by weight. The names of four preeminent chemists — Joseph Black, Henry Cavendish, Joseph Priestley, and Antoine Lavoisier — are entwined in the records of the first balloon flights, manned and unmanned. Their work opened the way to the first clear understanding of the chemical nature of matter.

The first military use of a balloon occurred in 1794 when the French Army used a balloon as an observation platform. The first parachute jump from a balloon was made in 1797 by Andre-Jacques Garnerin who dropped from about 6500 feet (1981 meters), using a chute of white canvas with a basket attached. In 1843 a commercial balloon air transport enterprise was established in London, but failed shortly after. In 1860 aerial photos of Boston and other cities were made from a balloon. Sponsored by *The New York Daily Graphic* newspaper in 1873, the first transatlantic flight was attempted in a 400,000 cubic foot (11,339 cubic meter) balloon carrying a lifeboat. The balloon collapsed during inflation, thus ending the project.

During the late 1880s and early 1900s, interest shifted from the balloon to the dirigible and, of course, to powered aircraft. See also **Dirigibles and Airships**. Serious interest in the balloon as a scientific tool was established about a half-century later.

Balloon Records

Captain Anderson and Major Kepner of the United States ascended to nearly 60,000 feet (18,288 meters) in a balloon in 1934. In November of 1935, Stevens and Anderson again ascended to an altitude of 73,000 feet (22,250 meters) within a period of 4 hours and during this flight gained considerable scientific information on the upper atmosphere, including air composition, spore distribution, and atmospheric effects on communications to and from the ground. These men also made cosmic ray measurements and observations on the spectral distribution of sunlight. The second flight was made in Explorer II, a balloon that had a volume of 3,700,000 cubic feet (104,784 cubic meters) when fully extended. The men were housed in a small globe-shaped gondola made of Monel metal and equipped with oxygen.

The ballooning altitude record is officially held by Cmdr. Malcolm D. Ross, USNR, who on May 4, 1961, in the Lee Lewis Memorial Winzen Research Balloon, achieved an altitude of 113,739.9 feet (34,668 meters) above the Gulf of Mexico. The distance record of 5208.67 miles (8382.4 km) is held by Ben Abruzzo in a flight from Nagashima, Japan to Covello, California on November 9–12, 1984. The duration record is held by Ben Abruzzo and Maxie Anderson in Double Eagle II in 1978, as described later.

An attempt to cross the Atlantic Ocean in a free balloon was made as early as 1881. This feat remained until October 1976 when Yost in his *Silver Fox* almost made it completely across the ocean. Yost flew 2740 miles (4409 kilometers) over a great-circle route from his point of launch (Milbridge, Maine) to touchdown (about 200 miles; 322 kilometers east of the Azores). The flight required 107 hours, 37 minutes and broke the previous record of 87 hours and 1896.85 miles (3052.03 kilometers) for balloons of unlimited size. The landing was short of a complete ocean crossing by about 700 miles (1126 kilometers). The *Silver Fox* was 80 feet (24.4 meters) high and contained 60,000 cubic feet (1700 cubic meters) of helium in a neoprene-coated nylon bag. The balloon and gondola combined weighed less than 2 tons, more than half of it ballast and expendable equipment. The balloon carried the American flag and the flag of the National Geographic Society, which furnished generous support for the venture.

The first successful crossing of the Atlantic Ocean occurred in August 1978. The *Double Eagle II*, with three balloonists (Abruzzo, Anderson, and Newman) aboard was launched from Presque Isle, Maine on August 11 and touched down near Miserey, France (just west of Paris) on August 17, after a flight of 137 hours, 6 minutes. The *Double Eagle II* had a capacity of 160,000 cubic feet (4531 cubic meters) of helium in a neoprene-coated nylon cloth envelope. See Fig. 2. The Pacific Ocean was successfully crossed in November 1981.

A record solo transatlantic balloon flight and the longest flight ever made by a single balloonist (3543 miles; 5700 km) was made by Joe W.

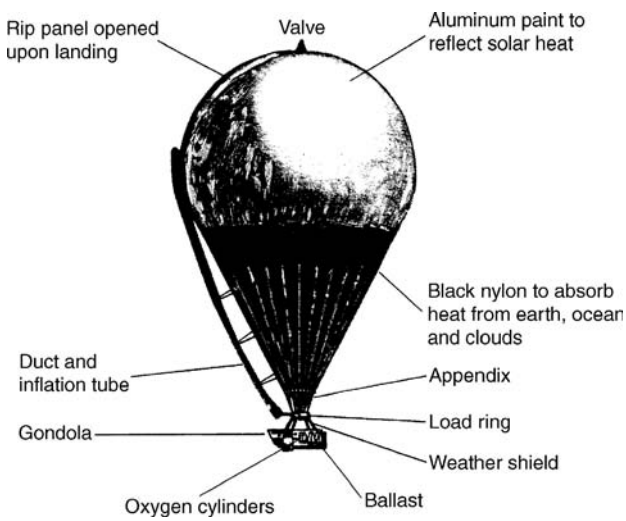

Fig. 2. Double Eagle II.

Kittinger, Jr. in the helium-filled *Rosie O'Grady*. The flight commenced at Caribou, Maine on September 14, 1984 and ended 83 hours and 40 minutes later at Cairo Montenotte, Italy. The altitude of the flight generally was between 10,000 and 15,000 feet (3,050–4,570 meters).

Richard Branson and Per Lindstrand made a flight of 2789.6 miles (4488.5 kilometers) from Sugarloaf, Maine, to Ireland in the hot-air balloon Virgin Atlantic Flyer on July 2–4, 1987.

The first transpacific hot-air balloon flight was made by Richard Branson and Per Lindstrand, originating in Miyakonyo, Japan, and ending near Yellowknife, Northwest Territories, Canada, a distance of about 6700 miles (10,780 kilometers). The flight occurred between January 15 and 17, 1991.

Balloons for Meteorological/Scientific Observations

Unmanned, instrument-carrying balloons can achieve altitudes of 30 miles (48 kilo meters). This is one-quarter of the height of orbiting satellites. At this range of altitude, balloons have the advantage of being above 99% of the earth's blanket of air. It is at this level that the complex chemical reactions that replenish or diminish the earth's ozone shield occur. Thus, balloon measurements are important to upper-atmosphere technology. Scientific balloons can be constructed, launched, and retrieved at a fraction of the cost of sending a satellite into space. It has been estimated that an entire balloon launching and research center can operate for a full year for much less than the cost of launching one satellite.

Balloon missions, of course, are shorter, measured in terms of just a few days. Prior to the NASA Shuttle Program, balloons were widely used for atmospheric research and still are, because of their ability to take samples and measurements of that part of the atmosphere that occupies the zone between high-flying aircraft and the altitude of satellite orbits. Also, with favorable conditions, the balloon remains within a reasonably tiny section of space, in contrast with the immense space coverage of aircraft and satellites.

The National Scientific Balloon Facility, located near Palestine in central Texas, has launched many hundreds of balloon missions. During the bleak years of the Shuttle Program, the values of balloon research were reemphasized.

Balloon launching facilities are relatively simple and inexpensive and thus may be of increasing value in studies of the atmosphere in the polar regions of the earth. The balloon technology for polar observations was tested as early as 1980, when Sidney and Eleanor Conn flew over the North Pole in the hot-air balloon. *Joy of Sound.*

In addition to meteorological and atmospheric observations, telescope-carrying balloons have been used a number of times in the past for studying infrared emanations from the sun and stars, as well as for cosmic ray investigations. Prior to the advent of satellite astronomy, observations of Mars, Venus, and other planets were made from balloons. Modern scientific balloons are constructed from microcrystalline polyethylene films up to 800 feet (244 meters) long. They are filled with inert helium gas.

Contemporary meteorological balloons range in capacity from 25,000 to 10,000,000 cubic feet (708 to 283,200 cubic meters) and some measure in excess of 200 feet (61 meters) in diameter, ascending to heights of 80,000 feet (24,384 meters) or more. In 1963, a balloon ascent to an altitude of 81,500 feet (24,841 meters) over New Mexico was made by a two-man crew. The unmanned 250-foot (76-meter) balloon, Stratoscope II, made observations of Mars from an altitude of 77,000 feet (23,470 meters) with a 36-inch (91-centimeter) reflecting telescope. This balloon, one of many launched from an atmospheric research center in Palestine, Texas at that time, carried a 6300-pound (2860-kilogram) instrumentation package. In another balloon, launched in 1965, telescopic pictures were obtained of Venus, at an altitude of 87,000 feet (26,518 meters). Prior to the manned space flight programs, balloons were sent aloft to obtain information on the upper atmosphere, including effects of the Van Allen radiation belt at high altitudes.

Some of the types of meteorological balloons used include:

Constant-Level or Constant-Pressure Balloon — designed to float at a constant-pressure level and used for measuring upper atmospheric conditions.

Pilot Balloon — used for computation of speed and direction of winds at higher levels.

Radiosonde Balloon — used to carry a radiosonde instrumentation package. Balloons have been developed which have a daytime bursting altitude of about 100,000 feet (30,480 meters) and nighttime bursting altitudes of about 80,000 feet (24,384 meters) above sea level. These balloons measure about 5 feet (1.5 meters) in diameter when first inflated, but may expand to about 20 feet (6 meters) before bursting at high altitude. The instrumentation package is returned to ground by parachute when the balloon bursts.

Balloons in Planetary Research

Planetary astronomers have found balloons especially useful in several research areas. Balloons have allowed researchers to rise almost to the top of the Earth's atmosphere so they could focus on distant objects without atmospheric influences. Balloons also have been useful in planetary missions for testing systems that would be used later in space and for maneuvering close to a planet's surface during a planetary mission.

An early instance occurred on May 31, 1954, when Charles Dollfus, a French aeronaut, ascended to 22,966 feet (7,000 meters) to help his astronomer son, Audoin, search for the presence of water vapor in the Mars atmosphere. Later, on April 22, 1959, Audoin reached 42,000 feet (12,802 meters) under a string of weather bureau balloons to study Venus without atmospheric interference.

NASA has used high-altitude balloons as test vehicles for technology that would fly on missions to the planets. In 1972, NASA used balloons to test a parachute system that would lower NASA's Viking Lander to the surface of Mars in 1976. A zero-pressure helium balloon carried the test Lander to a height of 92,000 feet (28,042 meters). From this altitude, the spacecraft was allowed to free fall into the desired subsonic speed. For the final test, a 34.6 million-cubic-foot (979,763-cubic-meter) balloon carried the simulated Mars entry vehicle to 120,000 feet (36,576 meters). Then a rocket shot the entry vehicle to 147,000 feet (44,806 meters), where the parachute system deployed, dropping the vehicle safely to Earth. The tests indicated that the Viking parachute system could be used in the Mars mission. When the mission was underway, the parachute system landed two instrumented, unmanned spacecraft on the surface of Mars to search for evidence of past, present, and potential future life on the planet.

Balloons were also used to help simulate the conditions the entry vehicle would experience on the Voyager mission to Mars. NASA used a zero-pressure balloon system consisting of a main balloon and a small launch balloon. The main balloon was 815 feet (248 meters) tall, about mid-way between the 555-foot (169-meter) height of the Washington Monument and the 1,250 feet (381 meters) of the Empire State Building. The balloon took the test entry vehicle to approximately 130,000 feet (39,624 meters) and released while pointing slightly upward. Then twelve small rocket motors accelerated the test vehicle to Mach 1.2 in level flight. This velocity simulated the maximum anticipated speed for the capsule when it would enter the Martian atmosphere, as well as demonstrating the pressure to which the vehicle would be exposed.

NASA also developed plans to use balloons to explore Venus with the aid of balloons, but it was the Soviets and French who implemented the plan. In December 1984, France and the Soviet Union launched a project designed to place two balloons into the sulfuric-acid clouds that circled Venus. The project would use balloons to study Venus' atmosphere much in the same way that the United States used balloons to study the Earth's atmosphere. Jacques Blamont of France worked with the Soviets on the mission, which would examine the winds that seemed to be whipping up the clouds.

France constructed two 27-foot (8.2-meter)-high balloons that carried the instruments to examine the wind changes in the clouds. The balloons were made of five layers of plastic. The innermost and outermost layers were made of Teflon to resist corrosion in the acid clouds.

Two Russian spacecraft, *Vega 1* and *Vega 2*, were launched on December 15 and December 21, 1984, respectively. Each had a descent module, which were metal spheres that contained a balloon package and a lander. The spacecraft reached Venus in June 1985. When the spacecraft dropped the metal spheres into the Venusian atmosphere, the descent modules separated and the balloons with their instruments were released. The balloon from Vega 1 entered the Venusian atmosphere on June 11, and the balloon from Vega 2 entered the atmosphere on June 15.

Released at an altitude of 37 miles (60 kilometers), the balloons started inflating with helium while they descended to the bottom of the Venusian sulfuric cloud layer. When they finished inflating, they climbed to 35 miles (56 kilometers). They drifted while they sampled horizontal and vertical wind changes in the clouds and measured the chemical makeup of the Venusian stratosphere and tops of clouds using an ultraviolet telescope. Vertical measurements showed the presence of wind vortices

more powerful than those of hurricanes on Earth. The balloons transmitted data for 46.5 hours. Both landers reached the surface of Venus and returned valuable data about the atmosphere of Venus and its soil composition. The two Vega spacecraft continued on their voyage to observe Halley's comet.

BALL, PEBBLE, AND ROD MILLS. Basically, all of these mills used for the size reduction of materials are comprised of a rotating drum which operates on a horizontal axis and is filled partially with a free-moving grinding medium which is harder and tougher than the material to be ground. The tumbling action of the grinding medium crushes and grinds the material by combination of attrition and impact. The grinding medium used may be a large number of round metal balls, operating in a drum with a metal lining. A conical ball mill is shown in Fig. 1. In the case of a pebble mill, a nonmetallic medium, such as flint, pebbles, or even large pieces of the material being ground, is used. Instead of a metallic lining, the lining may comprise flint or porcelain blocks. In a rod mill, the grinding medium consists of a series of metallic rods essentially as long as the mill cylinder. These rods rotate freely like balls or pebbles as the mill turns. Like ball mills, rod mills have metallic linings. Feed for rotating drums varies — from a maximum of $1\frac{1}{2}$-inch (3.8 centimeter) ring size downward. These units can be operated either in a batch or continuous mode. Grinding generally requires several hours to assure the necessary fineness within particle-size limits. Usually, oversize material will be returned continuously or handled in a subsequent batch. A rod mill is shown in Fig. 2.

BALSA TREE. Of the family *Bombaceceae* (silk cotton family), genus *Ochroma*, the balsa tree is found in the Central American tropics from southern Mexico through Ecuador and into northern Brazil. The balsa is a large, fast-growing tree, sometimes called corkwood or West Indian corkwood. Balsa wood is one of the lightest of the commercial woods, strong but pithy. At an air-dried moisture content of 12%, the specific gravity is only 0.13. The crushing strength with compression applied parallel to the grain is 1250 psi (8.6 MPa); the tensile strength with tension applied perpendicular to the grain is 115 psi (0.8 MPa). The wood from a 4-year-old tree will weigh about 8 pounds per cubic foot (128 kilograms/cubic meter). The wood becomes heavier as the tree grows older. In terms of strength/weight, balsa wood is stronger than some construction woods. It is particularly attractive when made into sandwich-type construction for its strength-weight ratio.

Balsa wood is composed largely of wood parenchyma, a tissue structure of thin-walled cells. This peculiar cellular structure makes the wood valuable for refrigeration insulation. Balsa sawdust also has been used for filling plastics because of its light weight. The cellular quality also makes the wood attractive for use in life preservers, vibration isolaters, floats, rafts, and for general use, cost permitting, where weight is the predominating factor.

Kari, a lightweight wood available in Japan from the *Paulownia tomentosa* tree competes to some extent with balsa wood. Samáuma also competes with balsa. See **Silk Cotton Trees**.

Species of balsa include: *Ochroma grandiflora* (Ecuador); *O. concolor* (Honduras and Guatemala), commercially called Barrios balsa; *O. limonensis*, called Limon balsa (Costa Rica and Panama); *O. obtusa*, called Santa Marta balsa (Colombia); and *O. velutina* or red balsa (Pacific coast of Central America).

BALTIMORE, DAVID (1938–). David Baltimore was an American-born biologist who shared the Nobel Prize for Physiology or Medicine in 1975 with Renato Dulbecco and Howard M. Temin for discoveries concerning the interaction between tumor viruses and the genetic material of the cell.

Born to a Jewish family in New York City, Baltimore grew up in Great Neck, Long Island, where his parents, prosperous from the garment business, had moved for the excellent public schools. Graduating from Swarthmore College, in 1960, he earned a PhD from Rockefeller University, in 1964, and then undertook postdoctoral studies at the Massachusetts Institute of Technology (MIT), Albert Einstein Medical College, and the Salk Institute. In 1967, he joined the MIT faculty, pursuing research on how RNA viruses interact with the cells they infect. One of his collaborators was Alice Huang, a biologist who had come to his laboratory at Salk and whom he married in 1968. Howard Temin had advanced the unorthodox idea that viral RNA generates complementary DNA then uses the machinery of the cell to produce new copies of itself. In 1970, Baltimore, following his own investigative line, demonstrated independently of Temin that RNA viruses do in fact contain an enzyme, reverse transcriptase, that catalyses the synthesis of DNA from RNA. See also **Temin, Howard Martin (1934–1994)**.

During the 1970s, Baltimore redirected the efforts of his laboratory — first into cancer, then into immunology, achieving over the years abundant important results in both areas. Research with the *Abelson leukemia virus*, for example, led to the discovery of genetic domains key to the intracellular signaling that governs the regulation of cell growth. Investigations of B cells yielded pioneering analyses of the mechanisms controlling the genetic rearrangements that determine how these immune cells differentiate so as to respond to specific infectious agents. All the while, Baltimore was drawn increasingly into the public affairs of science, helping to shape policy for recombinant DNA in the 1970s and for the Human Genome Project in the 1980s. After producing an influential report on AIDS for the National Academy of Sciences in 1986, he embarked on research into the dynamics of HIV. See also **Human Genome Project (The)**; and **Human Immunodeficiency Viruses (HIV)**.

In 1981, Baltimore had become director of the new Whitehead Institute for Biomedical Research, which was a partner of MIT and endowed with $135 million. Forging amicable relations between the two institutions, he provided a key link between basic molecular biology and the burgeoning

biotechnology industry, advising several successful startup companies and becoming wealthy in the process. In 1990, he was appointed President of Rockefeller University, launching an energetic program of structural and fiscal reform to bring the university's finances under control and to provide greater encouragement for junior faculty. He was forced to resign from the presidency in 1991 because of the so-called Baltimore Case — a controversy stemming from his support of a collaborator, Thereza Imanishi-Kari, who had been charged with scientific fraud but whose scientific honesty he had resolutely defended. In 1994, Baltimore returned to the MIT faculty. In 1996, when Imanishi-Kari was found to be innocent of all charges, he was restored to public grace. That year, he was appointed head of the newly created AIDS Vaccine Research Committee of the National Institutes of Health, and in 1997 he moved to Pasadena, California to become President of the California Institute of Technology. In 2000, he was awarded the United States' National Medal of Science. See also **Acquired Immune Deficiency Syndrome (AIDS)**; and **Biotechnology (The History)**.

BALUN. The name balun (balanced to unbalanced) is applied in general to devices used for the transformation from an unbalanced (coaxial) transmission line or system to a balanced (two-wire) line or system, in which the two terminals have equal impedance to ground.

BAMBOO. Of the family *Gramineae* (grass family), the tribe *Bambusae* comprises grasses that are particularly important to the economy of Oriental nations. The plants included in this group are of extremely variable nature, ranging from small inconspicuous species to the largest species of grass known, some having slender erect stems approaching 100 feet (30 meters) in height. Many are clambering vines that form dense impenetrable masses. All these grasses are characterized by jointed hollow stems having solid nodes, familiar to Western people in the common bamboo fishing pole. Among the Eastern peoples, bamboo is much more commonly used. The hollow stems may serve as pipes for conducting water, or as containers for storing water and other substances. Split stems may be flattened and used in constructing shelters, boats, or furniture. Some species yield a fibrous material which is used to manufacture a kind of paper. The young stalks of certain species have become an important foodstuff.

The semicarnivorous panda, whose native habitat is in China, relies upon a very heavy diet of bamboo, reportedly consuming as much as 25 pounds (11 kilograms) per day. When certain species of bamboo flower and die out (once every 15 to 120 years), there is a period of severe shortage for the pandas. See **Pandas**.

BANANA PLANT. Of the family *Musaceae* (banana family), genus *Musa*, the banana plant is a herbaceous perennial treelike tropical plant. Although a native of Asia, the plant is now grown in nearly all tropical areas. The fruit was first sent commercially to the United States from Central America in 1864. First found in Malaysia and the East Indies, the plant was introduced into Central and South American countries, such as Costa Rica, Honduras, Panama, Cuba, Jamaica, Haiti, Colombia, and Ecuador well over 100 years ago.

Most authorities agree that the center of origin of *Musa* genus plants was in southeastern Asia. Because of the strong association over the centuries of the banana with tropical America, some authorities have argued that the banana originated in that region. However, wild varieties of *Musa* have been found in Asia, whereas such has not been the case in the American tropics. Efforts continue to locate new sources of propagation material for the banana. One organization devoted to this is the Plant Production and Protection Division, Food and Agricultural Organization of the United Nations in Rome. Wherever possible, "seed" sources from areas that have been free from major diseases and pests in the past are sought.

The banana is frequently referred to in ancient Hindu, Chinese, Greek, and Roman literature. Mention of the banana is found in various sacred texts of Oriental cultures. Notable among these writings are two Hindu epics, the *Mahabharata*, the work of an unknown author, and the *Ramayana* of the poet Valmiki. There are also references to the banana in certain sacred Buddhist texts. These chronicles describe a beverage derived from bananas which Buddhist monks were allowed to drink. Yang Fu, a Chinese official in the second century A.D., wrote an *Encyclopedia of Rare Things*, in which he described the banana plant. The Greek naturalist philosopher Theophrastus wrote a book on plants in the fourth century B.C. in which he described the banana. His book is considered the first scientific botanical work extant. Pliny the Elder described the banana in A.D. 77.

Although there are numerous varieties of cultivated bananas, two of the principal varieties are *Cavendish* and *Gros Michel*.

The banana and plantain are cultivated widely and are grown nearly everywhere that suitable climatic and other environmental conditions prevail. The banana is among the most important of all commercial fruits, as it exceeds by quite a margin the production of the apple, for example, and comes close to equaling the combined production of all citrus fruits; if banana and plantain production figures are combined, the banana family well exceeds combined citrus fruit production.

The banana plant grows to a height of from 10 to 30 feet (3 to 9 meters). The plant has an underground root stalk with buds that form suckers as the plants develop on the plantation. The weak suckers require frequent pruning. The plant has a thick underground rhizome from which rises what seems to be a thick, erect stem. Actually this false stem is formed by the leaf bases which grow wrapped together to a height of 10 feet (3 meters), depending upon total height of plant (variety, growing conditions, etc.). From the upper portion, the large leaf blades spread out conspicuously, sometimes to a length of 10 feet (3 meters). Up through the center of the tube formed by the leaf bases, the flower stem pushes its way and bears bunches of inconspicuous small tubular flowers in the axes of large showy bracts. After fertilization of the flowers, the bracts fall off, and the whole cluster gradually hangs over due to the weight of the developing fruit. The fruit occurs in clusters (*hands*), the individual fruit being called a *finger*. There usually are about 7 to 15 fingers per hand. When green, the banana fruit contains an abundance of starch, some of which changes to sugar as the fruit ripens. Once harvested, the plant is cut down, but by retaining a large sucker, production can be kept active over a number of years. Botanically, the banana fruit is a berry, qualifying under the definition of a fruit that has a pulpy or fleshy pericarp, that is, the wall of a mature ovary and having one or more seeds in the flesh. The latter qualification is met by those wild banana species that do have true seeds in the flesh.

The time required for the fruit to reach the harvest stage varies from 3 to 4 months after flowering, and when the fruit is harvested the false or pseudo-stem is cut down. The large, conspicuous leaves of a mature banana plant are the last of a long series that starts with the formation of small-scale leaves as the young shoot or sucker emerges above the ground. If the sucker is developing from a deeply buried bud, the scale leaves are followed by long narrow "sword" leaves and then, as the plant grows older, by leaves that gradually increase in size and width until the typical mature leaves are formed. In contrast, if the sucker is arising from a bud at or above the surface of the ground, it is likely to produce broad leaves very early in its development.

A healthy, mature banana plant has from 11 to 14 functioning leaves, together with the sheaths of 12 to 16 leaves that developed earlier, but those blades wither and fall as the plant develops. The last leaf to develop is short, but almost as broad as the mature leaves immediately below it. Its sheath encircles the blossom stem as the latter emerges or "shoots" above the throat of the plant and its blade droops over the blossom but which bends downward in a few days from the weight of the rapidly developing inflorescence. The "protecting" or "follower" leaf gives the blossom bud a temporary degree of protection against the sun.

An extensive mass or matt of roots develops from the lower surface of the pseudo-bulb. They supply water and food materials to the aerial parts of the plant and also anchor and hold the pseudo-stem upright. The banana varieties grown for commercial use do not produce seeds. New plantations are established entirely from either whole pseudo-bulbs or portions of them containing one or more lateral buds or "eyes."

Two types of suckers are formed, the broad-leafed type from buds low down on the rhizome, and the sword sucker, with narrow, upright leaves from buds nearer to the surface of the soil. Both kinds of suckers are suitable as propagating material. The sucker should be severed from the parent plant close to the base of the old pseudo-stem and should be lifted

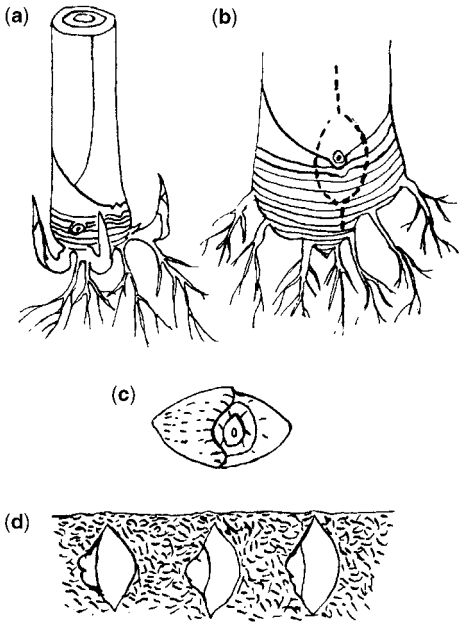

Fig. 1. Propagation of banana plant: **(a)** rhizome of banana showing suckers normally used for propagation; **(b)** dotted lines show how cut is made around dormant eye; **(c)** eye as it appears when removed from rhizome; **(d)** eyes planted in nursery bed, showing placement in vertical position.

from the soil with the root system intact. Another method of propagation is by means of eyes. See Fig. 1.

Although there are numerous species, that commonly exported is the *Musa paradisica*.

The leaf of some species is used in making cordage from a hemp-like fiber. In addition to table use, the banana is used in the preparation of flavorings. Vacuum dehydration of bananas yields banana crystals, a light brown powder used in ice cream, bakery products, and milk-based beverages.

The banana contains about 460 calories per pound (1014 calories per kilogram), highest among fresh fruits. The constituents are about 75% water, 1.3% protein, 0.6% fat, and the remainder carbohydrate.

The banana is considered an excellent food source, as evidenced by the following composition data prepared by the U.S. Department of Agriculture (1990):

Per 100 grams of Banana (Raw) Consumed)

Calories (kcal)	92.0	Ascorbic Acid (Vit. C) (mg)	9.1
Calcium (mg)	6.0	Thiamin (mg)	0.045
Iron (mg)	0.31	Vitamin B-6 (mg)	0.578
Magnesium (mg)	29.0	Folacin (micrograms)	19.1
Potassium (mg)	306.0	Vitamin A (Int'l. Units)	81.0

BAND EDGE ENERGY. The energy of the edge of the conduction band or valence band in a solid; that is, the minimum energy required by an electron in order that it may be free to move in a semiconductor or the maximum energy it may have as a valence electron.

BANDPASS FILTER. See **Filter (Communications System)**.

BANDSPREAD. In the finer grade of radio receivers, such as those used for communications purposes, it is desirable to be able to tune rapidly over a wide frequency range, yet be able to tune carefully to rather fine limits over a small range at any selected point in the wider range. This is accomplished by the band spreading tuning provided on such receivers. The usual arrangement is to have the wider range covered by conventional tuning capacitors, but have these paralleled by small variable capacitors that are tuned by the bandspread dial. Thus the complete range can be covered by one rotation of the main capacitors, while for any point at which they may be set the smaller ones can be used to give fine variation, thus giving, in effect, a spread-out tuning scale at this point. Other special circuit arrangements, such as tapping a capacitor across part of the tuning coil, are used to give the same result.

BAND THEORY OF SOLIDS. See **Solid-State Physics**.

BANDWIDTH. 1. In general, a range of frequencies specified by the number of hertz contained within the band or by the upper and lower limiting frequencies.

2. The range of frequencies that a device is capable of generating, handling, or accommodating; usually the range in which the response is within 3 dB of the maximum response. For example, the bandwidth of a modulated signal or of a bandpass filter is commonly defined by the frequencies at which the power spectral density is 3 dB (or a factor of 2) less than that within the band.

3. The amount of frequency space occupied by a signal and required for effective transfer of information by the signal. In data transmission, the greater the bandwidth, the greater the capacity to transmit data bits.

BANDWIDTH (Effective). 1. For a specified transmission system, the bandwidth of an ideal system which (a) has uniform transmission in its pass band equal to the maximum transmission of the specified system, and (b) transmits the same power as the specified system when the two systems are receiving equal input signals having a uniform distribution of energy at all frequencies. This may be expressed mathematically as follows:

$$\text{Effective bandwidth} = \int_0^\infty G\, df$$

where f is the frequency in cycles per second and G is the ratio of the power transmission at the frequency f, to the transmission at the frequency of maximum transmission.

2. For a bandpass filter, the width of an assumed rectangular bandpass filter having the same transfer ratio at a reference frequency, and passing the same mean-square value of a hypothetical current and voltage, having even distribution of energy over all frequencies.

BANK (Aircraft). 1. The position of an airplane when its lateral axis is inclined to the horizontal. A right or positive bank is the position with the lateral axis inclined downward to the right. 2. To incline an airplane laterally, i.e., to rotate it about its longitudinal axis. Banking of aircraft is necessary in making a turn so that the lift force normal to the plane of the wings produces the necessary component to counteract the centrifugal force acting on the aircraft in the turn.

BANKING (Curve). See **Superelevision**.

BANKS, JOSEPH (1743–1820). The only son of a wealthy Lincolnshire landowner, Banks inherited an ample fortune while attending Christ Church College, Oxford, which allowed him to pursue his passion for natural history. In 1768 he accompanied James Cook on the *Endeavour*'s exploring voyage to Australia, equipping himself lavishly and paying for scientific and artistic attendants. The voyage was full of adventure. The ship called at Cape Horn, Tahiti and New Zealand before arriving in Botany Bay (named in honor of Banks) on 27 April 1770. Banks collected plants, animals and ethnographic specimens in abundance, and recorded the customs of indigenous peoples, all of which made him a great authority after his return.

The voyage ended on 12 June 1771. Banks wished to accompany a second expedition but withdrew. He subsequently advised the British government about settlements in New South Wales, undertook agricultural improvements on his estates, expanded the role of the Royal Botanic Gardens at Kew, and became a friend of George III. In 1778 he became President of the Royal Society, holding this position until his death, and becoming notorious for ruling science as a despot. He married Dorothea Hugesson in 1779 and was created baronet in 1781. His house in Soho Square, London was a great centre for scientific activities, including his library and natural history specimens, which were bequeathed to Robert Brown, and then went to the British Museum. Banks' influence was

predominantly as a public figure. He published very little. See also **Plant Sciences (The History)**.

BANNER CLOUD. See **Clouds and Cloud Formation**

BANTING, SIR FREDERICK GRANT (1891–1941). A native of Ontario, Canada, Banting did his most important work in endocrinology.

Banting studied medicine at the University of Toronto. His studies were interrupted by the First World War, during which he served as a medical officer in the Canadian Army Medical Corps, and was awarded the Military Cross in 1918. After a short time in surgical practice, and a stint at the University of Western Ontario, he returned to the University of Toronto in 1921. There, with the support of J. J. R. Macleod, he pursued research on diabetes. He examined the problem of extracting pancreatic hormone, a potential therapeutic factor in diabetes. Basing his ideas on the work of earlier scholars, he and his research assistant, C. H. Best, succeeded in extracting the hormone from the pancreas of dogs in 1921; it was first tested on patients in January 1922. The extract, named insulin (from the Latin for island), was to transform the lives of many diabetics. See also **Diabetes Mellitus**; and **Insulin**.

For this research he received the Nobel Prize for Physiology or Medicine in 1923 along with John MacLeod of the University of Toronto. See also **Macleod, John James Richard**. In this same year Banting was appointed Professor of Medical Research; then in 1930 he became Director of the Banting and Best Department of Medical Research at Toronto. In 1930, the Banting Institute was founded in Toronto http://eir.library.utoronto.ca/insulin/application/scrapbooks.cfm.

In recognition of his services to medical science he was knighted in 1934. He continued research on many medical problems, among them silicosis and cancer. During the Second World War he again served with the Army, and was tragically killed in an air crash in 1941.

BANYAN TREE. See **Mulberry Family**.

BAOBAB TREE. Of the family *Bombacaceae* (silk cotton family), genus *Adansonia*, the baobab tree (*A. digitata*) is a familiar scene in much of the African savanna country. Because of its very large trunk, as compared with its height, and the relatively small amount of foliage, the tree sometimes has been termed pot-bellied. The trees usually occur singly and widely spaced on the savanna, thus adding to the effect of their unique shape. Travelogs of Africa almost invariably include a few views of the baobab to accentuate the African backdrop. Reasonably adult trees will attain a height of between 22 and 40 feet (6.6 and 12 meters). They live to an old age, 1000 years or more, but grow mainly in girth rather than in height. The trunk of a 30-year-old tree may be about 10 feet (3 meters) in diameter; a 1000-year-old tree may have a trunk diameter of 30 feet (9 meters). The roots sometimes reach out for 100 feet (30 meters) or more and the baobab is well known for its ability to store large quantities of water. In times of drought, elephants are known to chew the soft fibers of a fallen baobab to extract its watery juices. The large trunk can be easily carved to form a chamber which has been used for numerous purposes, including the storage of water by the people of the Sudan; for preserving cadavers for long periods of time without embalming by various natives. There are even unconfirmed reports that a hollowed-out baobab has been used as a temporary jail.

The tree bears long, oblong, and large fruit, sometimes called monkey bread of an acid taste. The mucilaginous pulp of the tree is sometimes eaten by natives. The bark yields a fiber that can be used for making cloth and rope and the timber can be used for various purposes. Baobab trees also are found on the island of Madagascar. These may have a girth of from 70 to 80 feet (21 to 24 meters) and hold lots of water.

The species is named for its founder, Michel Adanson, the French naturalist.

BAR. See **Units and Standards**.

BARABOO. A baraboo is a hill, mountain, or other eminence once buried by the deposition of sedimentary material about it and since exposed by the erosion of the younger beds. It is named from Baraboo, Wisconsin.

BARBER. See **Meteorology**.

BARBERRY SHRUB. Of the family *Berberidaceae* (barberry family), the barberries are small plants growing wild in the Northern hemisphere and in parts of South America. Many of them are spiny plants, which are sometimes cultivated as hedge plants. Examination shows that the leaves may vary from entire spiny-toothed structures to those reduced entirely to spines, only their position on the stem revealing the fact that they are leaves. The plants bear racemes of yellow flowers and, later, small red, yellow, or black berries, which make them attractive in appearance. The pollination in barberries is of especial interest. Each of the six stamens has a spot at the base of the filament sensitive to touch. When an insect, pushing about the base of the flower in search of nectar, touches this spot, the stamen moves violently, so that the sides of the insect's head are powdered with pollen. When the insect visits another flower, some of this pollen may be caught by the stigma, pollination thus being completed.

The American barberry (*Berberis canadensis*) ranges from Virginia southward through the Allegheny Mountains into Georgia and Missouri. The common barberry of Europe (*B. vulgaris*) was introduced into the United States many years ago as a hedge plant. Unfortunately, this species is the alternate host of *Puccinia graminis*, the organism that causes the destructive disease wheat rust. For many years, there has been a campaign to eradicate this species. Now much preferred as a hedge plant is the exceptionally beautiful *B. Thurnbergii*, a Japanese species, which bears bright scarlet berries. The berries of this shrub are edible and have been used in jams and jellies. Also of the genus is the trailing mahonia (*B. aquifolium*), a beautiful, low and trailing shrub found in the Rocky Mountains and Pacific northwest. The plant has leaflets something like a holly, a dark lustrous green turning to reds and yellows in the autumn. The flowers are a gold yellow, occurring in small clusters.

BARBERS'S ITCH. See **Folliculitis**.

BARBITURATES. Sedative drugs derived from barbituric acid. These drugs depress the central nervous system and act especially on the sleep center in the brain, thus their sedative and sometimes hypnotic effects. Barbital and phenobarbital are relatively long lasting in effects. Other drugs are more powerfully hypnotic and have a shorter action. In the treatment of epilepsy, phenobarbital is sometimes used. It has been shown to be an effective anticonvulsant, but produces drowsiness when given in large amounts. Barbiturates have been used in sleeping pills, but in recent years several other compounds also have been introduced for this purpose. Barbiturates induce a feeling of relaxation, usually followed by sleep. The drugs have been used to provide temporary respite in times of unusual emotional stress, but they must not be taken regularly as a substitute for a cure in chronic nervous tension. The drugs will only prolong the stress and encourage the patient to continue reliance on drugs instead of seeking a solution to emotional problems.

A few years ago, the Expert Committee on Drug Addiction of the World Health Organization advised the United Nations that barbiturates "must be considered drugs liable to produce addiction." Some persons develop a physical dependence on barbiturates; others may be able to stop using the drugs voluntarily. As in the use of other psychological supports, the need for continued barbiturates lies in the underlying personality disorder.

Because phenobarbital is frequently considered the drug of choice for treating young children with febrile seizures, a study was made, from November 1982 through December 1985, involving over 200 children between 8 and 36 months of age who had had at least one febrile seizure and represented a heightened risk of further seizures. The purpose of the

study was to determine possible behavioral and cognitive side effects of the drug. The report concluded: "This study found a depression of cognitive performance associated with phenobarbital, with indications of a disadvantage that outlasted the administration of the drug by several months and did not demonstrate a countervailing benefit." The report is discussed in some detail in the *N. Eng. J. Med*, 364 (February 8, 1990).

BARCHAN. A crescent-shaped dune or drift of wind-blown sand or snow; the arms of the crescent point downwind. Conditions under which barchans form are a moderate supply of material (sand or snow), and winds of almost constant direction and of moderate speeds.

BAR CHART. A method of representing relative magnitudes by lines or bars the lengths of which are proportional to the quantities involved. Simple bar graphs show individual quantities; compound bar graphs show complete quantities on a single bar, and are often referred to as percentage bar charts. See Fig. 1.

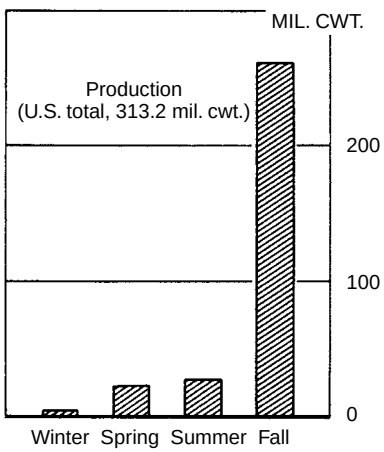

Fig. 1. Example of bar chart. (Production of Irish potatoes in the United States — quantity versus season.)

BARCROFT, JOSEPH (1872–1947). Joseph Barcroft was a British physiologist who was particularly interested in respiratory physiology. He also studied the effects of temperature, high altitude and exercise on respiration, the role of the respiratory pigment haemoglobin, and fetal physiology. Born in Northern Ireland into a Quaker family, Barcroft, or JB as he was widely known, was educated at the Leys School in Cambridge and read natural sciences at King's College, Cambridge, graduating in 1897. He spent almost his entire career in the Physiological Laboratory, Cambridge, becoming professor in 1926 in succession to John Newport Langley, and remaining there after his retirement in 1937. His research work, for which he was elected a Fellow of the Royal Society in 1910, concentrated on understanding respiratory function, studies that included physiological studies on experimental animals; observations on humans at extremes of altitude on expeditions in the Andes, in Tenerife and in Colorado; and significant biochemical work on the respiratory pigment haemoglobin and its binding and dissociation with oxygen. He summarized many of his contributions to this field in a book of 1914, The Respiratory Function of the Blood. After his death he was commemorated when Mount Barcroft in California was named in his honour in 1952, and the University of California established a high-altitude laboratory on its slopes.

In 1934 he published a further influential book, *Features in the Architecture of Physiological Function*, which summarized his views of integrative physiology; he was knighted the following year. During World War I he was asked to work on gas warfare at Porton Down, and he investigated the physiological effects of a variety of agents, including chlorine, phosgene and other poisonous gases, often experimenting on himself. After the war he returned to Cambridge and to his respiratory work, although he retained a connection with Porton, and during the early part of World War II he continued the work he had previously pursued there. In the final years of his life he concentrated on the physiology of the developing fetus, working principally on goats and sheep, and using a caesarean section surgical technique, Barcroft measured fetal blood volume and placental blood flow, the transfer of gases across the placental membrane, the control of respiration and movement, and growth parameters of the fetus, findings that he encapsulated in his final book, *Researches on Pre-Natal Life* (1946). See also **Physiology (The History)**.

BARDEEN AND BRATTAIN THEORY. The observation that a metal in contact with a semiconductor prefers to emit "holes" rather than electrons is explained by the tendency for electrons to remain bound in surface states near the junction.

BARDET-BIEDL SYNDROME (BBS). Bardet-Biedl syndrome is a rare genetic disorder that affects the brain and can cause multiple physical problems including a deterioration of the intellect and neurological functions. The syndrome sometimes affects eyesight with a condition called rod-cone dystrophy, a degeneration of light-sensitive cells in the periphery of the retina. This eye disorder causes night blindness, tunnel vision, decreased visual acuity, and photophobia (extreme sensitivity of the eyes to light). Other symptoms of Bardet-Biedl syndrome may include extra toes and/or fingers, mental retardation, kidney disease, and obesity.

Bardet-Biedl syndrome is characterized as recessively inherited. In other words, neither parent exhibits characteristics of the disorder, but both carry the recessive gene that causes the disorder. Parents who have one affected child run a 25% chance in each additional pregnancy of the condition occurring again. There is also a two in three chance that children of subsequent pregnancies, although not affected, will be carriers of the recessive gene. The syndrome is rare because the recessive gene is only carried by approximately 1 in 179 people. Therefore, a person carrying the gene is unlikely to conceive children with another person who also carries the gene.

Bardet-Biedl syndrome can be difficult to diagnose, especially in the young, because many of the symptoms are not yet obvious and may vary considerably from one patient to another. Because there is no known cure, physicians concentrate on the treatment of specific organs and systems.

Most victims of Bardet-Biedl syndrome experience progressive retinal degeneration, with night blindness usually appearing by age 9 and legal blindness often occurring by age 15. Other visual symptoms may include nystagmus (involuntary eye movement), nearsightedness, strabismus (cross-eye), glaucoma, and cataracts.

There is no known treatment for the progressive vision problems that often occur in persons with Bardet-Biedl syndrome. However, there is much that can be done to prepare for a life with low vision. An ophthalmologist should be consulted to diagnose the specific problems accurately, and other vision professionals, including low vision specialists, can assist in making life easier for sufferers.

- Some of the other common characteristics of Bardet-Biedl syndrome are:
- Extra fingers or toes, ranging from a single skin tag to a fully formed digit.
- Short, stubby fingers and/or toes, more frequently in the feet than in the hands.
- Webbing of toes.
- A high frequency of obesity, usually beginning at 1 or 2 years of age.
- Learning difficulties.
- Small testes and genitalia in men.

Vision Rx, Inc., Elmsford, NY

BARDHAN-SENGUPTA SYNTHESIS. Phosphorus pentoxide and other powerful dehydrating agents act upon 2-beta-phenethyl-1-cyclohexanol to form octahydrophenanthrene compounds.

BARFF PROCESS. A process for oxidizing the surface of metals, by the action of superheated steam, to increase their resistance to corrosion.

BARITE. The mineral barite is barium sulfate, $BaSO_4$ crystallizing in the orthorhombic system. It may occur as tabular crystals, in groups, or lamellar, fibrous and massive. Barite has two perfect cleavages, basal and prismatic; hardness, 3–3.5; specific gravity, 4.5, which has led to the term heavy spar, occasionally used for this mineral. Its luster is vitreous; streak, white; color, white to gray, yellowish, blue, red and brown; transparent to opaque. It sometimes yields a fetid odor when broken or when pieces are rubbed together, due probably to the inclusion of carbonaceous matter. It is used as a source of barium compounds.

Barite is a frequently occurring gangue mineral and is found also in large masses in sedimentary rocks. It occurs in many places in Europe, including the Czech Republic and Slovakia, Germany, France, Spain and England; in the United States, New York, Connecticut, Pennsylvania, Virginia, Michigan, Missouri, New Mexico, Oklahoma, Utah, Colorado, South Dakota, Georgia and Tennessee. In Canada it occurs in Ontario and in Nova Scotia.

The name of this mineral derives from the Greek word meaning heavy.

BARIUM. [CAS: 7440-34-3] Chemical element symbol Ba, at. no. 56, at. wt. 137.33, periodic table group 2 (alkaline earths), mp 725 °C, bp 1640 °C, density 3.5 g/cm^3 (20 °C). Body-centered cubic crystal form. Naturally occurring isotopes are ^{130}Ba, ^{130}Ba, ^{134}Ba, ^{135}Ba, ^{136}Ba, ^{137}Ba, and ^{138}Ba. Barium metal is comparatively soft and ductile and capable of mechanical working. Barium metal and all barium compounds are highly toxic to humans, although barium sulfate (because of its insolubility in H_2O and body fluids) can be ingested without harm and is widely used as an opaque medium in x-ray diagnostic studies of the body. First ionization potential 5.21 eV; second 9.95 eV. Oxidation potentials $Ba \rightarrow Ba^{2+} + 2e^-$, 2.90 V, $Ba + 2OH^- + 8H_2O \rightarrow Ba(OH)_2 \cdot 8H_2O + 2e^-$, 2.97 V. Other important physical properties of barium are given under **Chemical Elements**.

Barium occurs chiefly as sulfate (barite, barytes, heavy spar, $BaSO_4$), and, of less importance, carbonate (witherite, $BaCO_3$). Georgia and Tennessee are the principal producing states. The sulfate is transformed into chloride, and the electrolysis of the fused chloride yields barium metal. See also **Barite**; and **Witherite**. Barium ores are mined chiefly as a source of barium compounds because very little metallic barium is consumed commercially. The metal is obtained by thermal reduction of the oxide, using aluminum metal at a high temperature and under vacuum in a closed retort: $4BaO + 2Al \rightarrow BaOAl_1O_3 + 3Ba$. The gaseous barium produced is recovered by condensation.

As is to be expected from its high electrode potential (2.90 V) barium, like strontium and calcium, reacts readily with the halogens, oxygen and sulfur to form halides, oxide, and sulfide, as well as with nitrogen and hydrogen at higher temperatures to form the nitride and hydride. In all its stable compounds it is divalent. It reacts vigorously with water, displacing hydrogen to form the hydroxide. Barium peroxide is formed on treatment of the hydroxide with hydrogen peroxide in the cold and also by direct combination of oxygen and barium oxide or metal. The peroxide prepared in the latter way is frequently paramagnetic because of the presence of some superoxide, $Ba(O_2)_2$. Barium exhibits little tendency to form complexes, the amines formed with NH_3 being unstable and the β-diketones and alcoholates are not well characterized. Barium metal solutions in liquid NH_3 solution yield $Ba(NH_3)_6$ upon evaporation. Common compounds of barium are:

Barium acetate, [CAS: 543-80-6] $Ba(C_2H_3O_2)_2$, white crystals, solubility 76.4 g/100 ml H_2O at 26 °C, formed by reaction of barium carbonate or hydroxide and acetic acid.

Barium carbide (acetylide), [CAS: 50813-65-5] BaC_2 black solid, by reaction of barium oxide and carbon at electric furnace temperatures, reacts with H_2O; yielding acetylene gas and barium hydroxide.

Barium carbonate, [CAS: 513-77-9] $BaCO_3$, white solid, insoluble ($K_{sp} = 5.13 \times 10^{-9}$), formed (1) by reaction of barium salt solution and sodium carbonate or bicarbonate solution; (2) by reaction of barium hydroxide solution and CO_2. With excess CO_2 barium hydrogen carbonate, $Ba(HCO_3)_2$, solution is formed. Barium carbonate decomposes at 1450 °C.

Barium chloride, [CAS: 10326-27-9] $BaCl_2 \cdot 2H_2O$, white crystals, solubility 31 g/100 ml H_2O at 0 °C, formed by reaction of barium carbonate or hydroxide and HCl.

Barium chromate, [CAS: 10294-40-3] $BaCrO_4$, yellow precipitate, $K_{sp} = 1.17 \times 10^{-10}$, formed by reaction of barium salt solution and potassium chromate solution.

Barium cyanamide, $BaCN_2$, formed in a mixture with barium cyanide, $Ba(CN)_2$, by heating barium carbide at 800 °C with nitrogen gas. Fusion of the cyanamide-cyanide mixture with sodium carbonate converts it entirely to cyanide.

Barium nitrate, [CAS: 12047-79-9] $Ba(NO_3)_2$, white crystals, solubility 8.7 g/100 ml H_2O at 20 °C, formed by reaction of barium carbonate or hydroxide and HNO_3.

Barium oxide, BaO, white solid, mp about 1900 °C, reactive with H_2O to form barium hydroxide. Barium peroxide, $BaO_2 \cdot 8H_2O$, white precipitate, formed by reaction of barium salt solution and hydrogen or sodium peroxide, yields anhydrous barium peroxide upon heating at 100 °C in a current of dry air. Anhydrous barium peroxide is also formed by heating barium oxide in air or oxygen under pressure (at somewhat over one atmosphere pressure) and temperature of 400 °C.

Barium oxalate, [CAS: 516-02-9] BaC_2O_4, white precipitate, $K_{sp} = 1.1 \times 10^{-7}$, formed by reaction of barium salt solution and ammonium oxalate solution.

Barium sulfate, [CAS: 1727-43-7] $BaSO_4$, white precipitate, $K_{sp} = 8.7 \times 10^{-11}$, formed by reaction of barium salt solution and H_2SO_4 or sodium sulfate solution, insoluble in acids; by heating with carbon yields barium sulfide.

Barium sulfide, [CAS: 21109-95-5] BaS, grayish-white solid, formed by heating barium sulfate and carbon, reactive with H_2O to form barium hydrosulfide, $Ba(SH)_2$, solution. The latter is also made by saturation of barium hydroxide solution with H_2S. Barium polysulfides are formed by boiling barium hydrosulfide with sulfur.

Uses of Barium. The major use of barium metal for a number of years has been as a getter for oxygen in electronic vacuum tubes. A layer of the metal is deposited inside the glass envelope of the tube. Minute quantities of gases that leak into the tube react with the barium layer to form compounds. If the gases remained free, they would alter the conductance of the tube and cause deterioration of its performance.

BARK. All tissues of woody stems or roots that occur outside the cambium are collectively known as bark. The major functions of the bark are translocation and storage of organic materials, water storage and wound healing, protection from herbivores and pathogens, isolation from environmental hazards, and in the shoot, photosynthesis. In many leafless or almost leafless plants, all or most of a plant's photosynthesis is performed by the bark. An ecologically important function of bark is to protect trees from fires. Thick barks, being poor conductors of heat, isolate the sensitive live tissues of many tree species from fires. See also **Epidermis (Plant)**.

Structure and Development

The bark includes primary and secondary phloem, cortex, first periderm, sequent periderms (rhytidome) and tissues formed by dilatation growth. The structure of the bark in roots of a given species is usually somewhat less complicated than in the shoot, and the description here refers to the shoot rather than to the root. The wealth of known structures and functions of the bark is never found in a single species, and there are also many variations at different ages and with changing growth conditions in the

same individual. Additional variation is expressed following wounding or pathogen attacks.

In woody plants, two regions are distinguished within the bark: the inner bark, which is alive and where certain cells may redifferentiate and become meristematic; and the outer, dead bark cut off from live tissues by dead isolating cork layers – the rhytidome. We distinguish between primary bark (originating from primary meristems – protoderm, ground meristem and procambium) and secondary bark (originating from secondary meristems — the vascular cambium, the phellogen, and dilatation meristem).

The contribution of the primary meristems to the primary bark is as follows. The protoderm gives rise to the epidermis, which may exist for many years or may be replaced by cork (periderm). The ground meristem gives rise to the cortex, made of parenchyma, collenchyma, fibers, sclereids, idioblasts of various types, resin ducts or laticifers. The procambium gives rise to the primary phloem including the primary phloem fibers. In a number of plants, the border between the cortex and the primary phloem is marked by the starch sheath, a layer rich in starch grains, considered to be homologous with the endodermis of the root. An endodermis, with its typical casparian strip, is known from the shoot of only a small number of plants. In addition to these components, in shoots, leaf traces composed of xylem and phloem cross the cortex before they fuse with the central vascular cylinder. See also **Cork**.

The vascular cambium (a secondary lateral meristem) is the origin for the secondary phloem. The distinction between the primary and secondary phloem is easy in most gymnosperms and dicotyledons since the secondary phloem has a radial component (the vascular rays) in addition to the axial component, whereas the primary phloem does not include rays. However, hundreds of species produce secondary phloem with no rays as a special adaptation. The secondary phloem of many species has many bands of fibers (bast fibers). When cambial activity produces large amounts of xylem, the phloem is pushed outward, and the old, non-conducting and soft sieve cells collapse and flatten, but the bands of fibers, axial parenchyma and rays remain intact.

In many conifers, resin ducts develop in both the primary and secondary bark. They produce resin with species or even genotype-specific chemical composition. In many angiosperms, laticifers or gum ducts develop and produce special resins and latexes. Wounding results in the differentiation of additional resin ducts in conifers and gum ducts in many dicotyledons. See also **Conifers**.

At a certain stage of shoot development, a periderm (cork tissue) may appear. The periderm is a secondary tissue formed from a secondary meristem — the phellogen, also known as cork cambium. The function of the periderm is to isolate and thus protect the live tissues from both biotic and abiotic damaging factors. In certain trees, the periderm may reach a thickness of dozens of centimeters, but usually it is only several millimeters to several centimeters thick. A well-known case is the giant sequoia of the western USA, in which bark thickness of mature trees ranges from 25 to 80 centimeters (10 to 31.5 inches). The periderm is composed mostly of cork (phellem) cells, which die after differentiation, and their secondary cell walls are rich with suberin. The periderm also includes a certain amount of parenchyma (phelloderm) cells, and sometimes, for instance in pines, layers of hard, heavily lignified sclereids within the phellem zone.

In many plant species, there are many lenticels, which serve as gas exchange shafts through the almost impermeable cork. Lenticels are made of many loosely arranged cells that form a continuity of intercellular spaces with the inner tissues and appear as dots and stripes on the bark surface.

Initials of the phellogen mostly divide outward to produce phellem (cork) cells, but a small fraction of its cell divisions are inward, to form the parenchymatic phelloderm. Derivatives of the phellogen are usually arranged in radial files. Initiation of periderm starts at different distances from the shoot apex and from different tissues. The site of phellogen initiation is in the pericycle in the roots, but in the shoot it can initiate in the epidermis, subepidermis or in much deeper layers, such as the cortex or old phloem. Although for each organ and species there is a typical cell layer in which phellogen is initiated, there are many exceptions. Genetic, physiological and environmental factors largely influence the timing and location of phellogen initiation in plants. In some plants, phellogen initiation occurs within a short time (only a few days) after an organ is formed, but in others it can be delayed for decades. In some plants, only a first periderm is formed, and this periderm may continue its activity for the rest of the plant's life. The best-known case of such periderm is the cork oak, from which most of the global commercial cork originates.

In many woody plants, there is a second stage of cork formation — the rhytidome or subsequent periderm. In plants that form subsequent periderms, live parenchyma cells of the secondary phloem redifferentiate and form an internal zone of phellogen. The activity of this phellogen produces a layer of cork cells that isolate all tissues outward to them from nutrients and so cause them to die. All tissues (cork and other tissues) found outward from the innermost subsequent periderm compose the rhytidome. See also **Parenchyma**.

In several tropical tree species, especially trees of the savannah, spines develop on the surface of the trunks. Usually these spines are made of a special type of cork that develops from islands of phellogen.

In trees, bark tissues usually comprise a much smaller fraction than wood. Similarly, the effort to study bark development, anatomy and physiology is only a small fraction of what is given to wood production. Thus, we do not know much concerning bark biology. The best model plant, *Arabidopsis thaliana*, has both primary and secondary bark, although it is a rather small annual. Certain aspects of bark development, however, can be studied in this plant. The secondary phloem, which composes most of the inner bark in trees, is formed by cambial activity that usually produces 5–15 times more secondary xylem than phloem. Some species, i.e. the cork oak of the Iberian Peninsula, form growth-rings in the cork. However, dating various events using cork rings is not a common practice. The structure of the periderm influences the morphology of the outer surface of woody plants, especially trees. The bark can be smooth or covered by scales of various shapes and sizes. It can peel in small, medium or very large sheets or blocks and can differ in color. The functionality of the specific types of bark structure, morphology, shape and size of scales, color and chemistry are almost unknown.

Regulation of Cork Development

Several environmental and endogenous conditions induce cork formation: submergence in water, direct strong sun irradiation, mechanical and biotic wounding, and ageing. All these factors are known to increase the production of the gaseous phytohormone ethylene. It was therefore proposed that ethylene is the major activator for phellogen initiation and activity. Since the cork layer formed is almost impermeable to gases, as a cork layer is formed, the inner cell layers are exposed to increasing levels of ethylene, and more cork formation is induced. In many plant species, there is a gap in phellogen initiation around buds in the nodal region, or a cork-free region in stems and branches beneath buds and major veins of leaves. Therefore, it was proposed that the basipetal polar auxin transport inhibits cork formation in these regions. These cork-free regions later enable suppressed buds to develop quickly and form new branches after damage to the canopy, and not to be disturbed by a heavy, hard layer of cork.

Dilatation

When trees and shrubs or even thick annuals grow in diameter, the outer tissues expand to a certain but limited degree. With additional diameter growth, there is a danger that cracks will be formed, and the sensitive inner tissues will be exposed to biotic and abiotic agents that can endanger the plant. To avoid the formation of such cracks, a special tissue is formed in the outer bark — a dilatation tissue. Dilatation is the outcome of one or two processes that co-occur in many species. The first process is dilatation growth as the result of cell expansion. Certain parenchyma cells of the cortex, of the axial phloem parenchyma or the phloem ray parenchyma expand to keep the bark intact. In other cases, groups of these cells enter a phase of cell divisions and form a dilatation meristem. When dilatation occurs in the phloem rays, a distinctly funnel-shaped phloem ray dilatation occurs. Dilatation may be very irregular, resulting in the formation of whirled tissues and various shapes of rays. Similarly, meristematic zones in various other orientations and from other origins occur within the bark in the process of dilatation. Dilatation activity results in production of parenchyma, and later, many of these parenchyma cells may redifferentiate to sclereids. Dilatation activity is suppressed in the lower side of leaning trunks, probably by the higher-than-usual auxin levels. Application of ethylene, wounding, or environmental conditions that induce ethylene production result in higher dilatation activity.

Uses of Bark

Products made of bark have been important since ancient times. Several plants are famous for their bast fibers (secondary phloem fibers): flax,

hemp, jute, ramie and kenaf. Their fibers are used for textiles, cordage, matting, fishing nets, sails, sacks, paper production, etc. Before the invention of plastics, these and other plant fibers were of the utmost importance. Cork from the cork oak (*Quercus suber*) and a long list of secondary cork-based products are used all over the world. Sealing wine bottles is only a small fraction of the uses of cork. Tanning hides with bark tannins to produce leather has been practiced for millennia. Before the age of rubber and plastics, leather was extremely important, and its production needed bark tannins. Rubber is mainly produced from the latex exuded from the artificially wounded bark of *Hevea brasiliensis*. Many other species produce latex in the bark, but only a small number of species are used for rubber production. Several barks provide chemicals used for medicine. Quinine, the cure for malaria, still a major killer in the tropics, is produced from the bark of several species of the genus *Cinchona*. Taxol, a drug used against several types of cancer, is extracted from the bark of the Pacific yew (*Taxus brevifolia*). Curare, probably the best known muscle-relaxing poison and a source for medicines, is produced by mixing barks of several tropical species. Cinnamon, camphor, and several other spices are also produced from tree barks.

BARK BEETLE *(Insecta, Coleoptera)*. A small beetle of cylindrical form that burrows in the sapwood and inner bark of trees and logs, forming characteristic patterns. This habit also gives the name engraver beetle to these insects. Most of the numerous species infest forest trees but a few attack fruit trees. Together with the timber beetles and a few species which attack herbaceous plants they make up the family *Scolytidae*. Destruction of standing timber by these beetles has been estimated as high as 5 billion board feet (1.2 billion cubic meters) per year.

BARKHAUSEN EFFECT. A series of minute "jumps" in the magnetization of iron or other ferromagnetic substance as the magnetizing force is continuously increased or decreased; discovered by H. Barkhausen in 1919. The effect may be observed by winding on the specimen, along with the magnetizing coil, a secondary coil connected to some sensitive detector of current fluctuations, such as an oscillograph or an audio amplifier. As the magnetizing current is steadily increased, the current in the secondary circuit, instead of being constant, exhibits a succession of small, sharp peaks or maxima, which the amplifier reveals by a faint clicking or snapping sound. See also **Ferromagnetism**; and **Magnetism**.

BARK LOUSE *(Insecta, Homoptera)*. A scale insect. These insects are minute creatures with sucking mouths. They spend most of their lives attached to the leaves, stems, or roots of plants. The name scale insect is due to the common secretion of a scale that conceals the body of the insect. There are many species, of which some, like the oyster-shell bark louse, *Lepidosaphes ulmi*, and the San Jose scale, *Comstockaspis perniciosa*, are important enemies of fruit trees.

Some scale insects produce substances of commercial value, notably cochineal and shellac.

BARLEY. Of the family *Gramineae* (grass family), subfamily *Festucoideae*, tribe *Horeade*, and genus *Hordeum*, barley is an annual cereal grass of major worldwide importance, rating fourth in most lists of cereal crop statistics. Because of its outstanding tolerance to a wide range of climates and altitudes, barley is cultivated in many regions of the world, as later delineated. Barley produces stalks up to 3 feet (0.9 meter) in height. The inflorescence is a close spike. There is much evidence of the antiquity of this plant. Remains found in the ruins of lake dwellings in Switzerland indicate an association of barley with Stone Age culture. An ancient Chinese text establishes the culture of barley as early as 2000 B.C. The plant was cultivated in ancient Egypt by the Greeks and Romans and is mentioned in *Exodus* 9:31, "And the flax and the barley was smitten: for the barley was in the ear, and the flax was boiled. But the wheat and the rye were not smitten; for they were not grown up."

Primitive peoples in Europe used barley for food, as do many modern races. However, lacking gluten, it is not well suited for making light breads, a fact that has kept barley from being of greater popularity among cultured races. Although barley is used directly in some breakfast cereals, soups, and other prepared food products, barley is consumed mainly as a source of malt (for the brewing industry) and as a major feed for animals. Barley is an excellent feed for finishing beef cattle. Its feeding value is about 90% that of maize (corn). A great advantage of barley is that it is the earliest maturing of the small grains. This makes it adaptable to a double-crop system, such as barley and soybeans, or barley and grain sorghum. Barley is an excellent winter grain crop for many regions, such as Arizona and California in the southwestern United States and in the southeastern United States, particularly in the upper Coastal Plain in the northern reaches of Georgia. Compared with most other cereal crops, barley is superior in terms of drought resistance.

A general breakdown of the uses of barley (in the United States) is: seed (10%); food products for human consumption (10%); malt production (20%); animal feeds (60%). Barley has a feeding value of about 95% that of maize (corn). Barley is used for hay in some areas and as a winter cover crop in the southeastern United States.

Linnaeus described barley in 1754 as: "Genus *Hordeum*: Spike indeterminate, dense, sometimes flattened, with brittle, less frequently tough awns. Rachis tough or brittle. Spikelets in triplets, single-flowered but sometimes with rudiments of a second floret. Central florets fertile, sessile or nearly so, lateral florets reduced, fertile, male or sexless, sessile or on short rachillas. Glumes lanceolate or awnlike. The lemma of the fertile flowers awned, awnleted, awnless, or hooded. The back of the lemma turned from the rachis. Rachilla attached to the kernel. Kernels oblong with ventral crease, caryopsis usually adhering to lemma and palea. Annual or perennial plants."

To accommodate for cultivated types, Aberg and Wiebe (U.S. Department of Agriculture) added the description: "Summer or winter annuals, spikes linear or broadly linear, tough or brittle. The central florets fertile, the lateral ones fertile, male, or sexless. Glumes lanceolate, narrow or wide, projecting into a short awn. The lemma in fertile florets awned, awnleted, awnless, or hooded, the lemma in male or sexless florets without awns or hoods. Kernel weight from 20 to 80 milligrams. The chromosome number in the diploid stage 14."

Reference to Figs. 1 and 2 will assist in interpreting the foregoing technical descriptions. *Rachis* = principal stem of flower; *floret* = flower; *lemma* = sheath; *sessile* = attached to main stem; *lanceolate* = narrow and tapering (lancelike); *glume* = husk or chafflike bract; *awn* = bristly fibers or bead on head.

The culm (jointed stem) of the barley plant is made up of from five to seven hollow, cylindrical internodes that are separated by solid, somewhat larger joint nodes from which the leaves arise. The length (height) of the culm may range from about 8 inches (20 centimeters) to as much as 5 feet (1.5 meters), depending upon variety and growing conditions. There are usually from three to six culms per plant if a normal seeding rate has been used. The leaf sheath is smooth or glabrous, although covered with hairs in a few varieties.

The botany and taxonomy of barley are complex topics because of the several species and hundreds of varieties, each exhibiting minor differences sometimes difficult to distinguish. Barley is considered by most authorities to be a plant native to the Orient, particularly of western Asia where it grows wild today. Wild species also are found in other regions of the world, including North America. When young, such wild plants can be used for forage, but as they become mature, they are regarded as rather aggressive weeds. Some of the wild species include:

- *Hordeum jubatum*, which has mature spikes with sharp-pointed joints that can be injurious to livestock.
- *H. jubatum, H. montansse*, and *H. nodosum*, perennial wild species.
- *H. adscendens, H. gussuoneanum, H. murinum*, and *H. pusillum*, annual species that frequently occur in pastures of the southwestern United States.

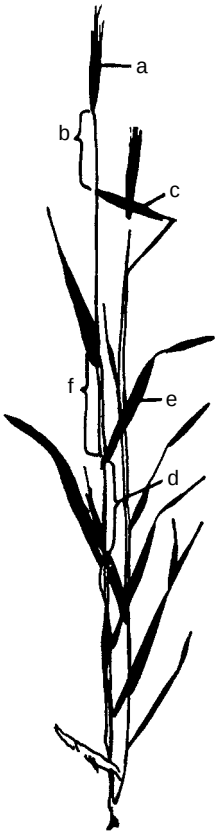

Fig. 1. Barley plant: **(a)** Spike; **(b)** exposed upper peduncle; **(c)** flag leaf; **(d)** sheath; **(e)** leaf blade, third from top; **(f)** internode below peduncle. (*After USDA diagram*.)

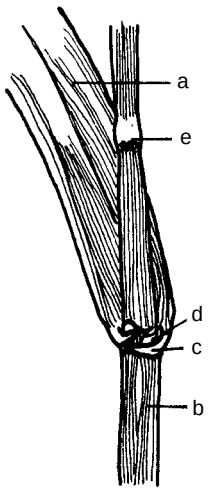

Fig. 2. Culm of barley plant partially shown: **(a)** Leaf blade; **(b)** leaf sheath; **(c)** auricle; **(d)** ligule; **(e)** node. (*After USDA diagram*.)

H. agriocrithom, a wild species commonly found in the highlands of eastern Tibet. *H. spontaneium* is another common wild species. It is interesting to note that these two species have 14 diploid chromosomes and can be readily crossed with cultivated varieties.

In the earliest cultivated varieties of barley, the flower possessed stout barbed awns, which were disagreeable to persons who handled the grains and also caused serious difficulties when the grain was fed to livestock. As the result of plant breeding in the U.S.S.R. many years ago and then later carried out by scientists elsewhere, these awns were eliminated or modified, leaving a smooth-fruited variety.

In the mature barley grain, the aleurone layer is usually three cells in thickness, and the embryo is very small.

BARLOW RULE. The volumes of space occupied by the various atoms in a given molecule are approximately proportional to the valences of the atoms; whenever an element exhibits more than one kind of valence the lowest value is generally selected.

BARN. See **Neutron**; and **Units and Standards**.

BARNACLE *(Crustacea, Cirripedia).* Sessile marine animals wholly unlike the more common crustaceans in appearance. Some are parasitic, some burrow in the shells of marine animals, and some attach themselves to submerged objects. The last habit is economically important since it results in the fouling of ships' bottoms and entails the expense of periodical cleaning.

BAROCLINIC. 1. The variation with depth of motions associated with variation of density with depth. The baroclinic component of the velocity is the total minus the barotropic component. In a baroclinic state, neutral surfaces are inclined to surfaces of constant pressure. The baroclinic torque vector is proportional to the vector cross product and is responsible for generating vertical shears associated with baroclinic flow.

2. Of, pertaining to, or characterized by baroclinity. See also **Baroclinity**.

BAROCLINIC ATMOSPHERE. An atmospheric state in which density depends upon both temperature and pressure and in which the geostrophic wind varies with height and is related to the horizontal temperature gradient via the thermal wind equation.

BAROCLINIC DISTURBANCE. Any migratory cyclone more or less associated with strong baroclinity of the atmosphere, evidenced on synoptic charts by temperature gradients in the constant-pressure surfaces, vertical wind shear, tilt of pressure troughs with height, and concentration of solenoids in the frontal surface near the ground. Also called *baroclinic wave*. See also **Baroclinity**.

Baroclinic disturbances play an important role in atmospheric energy conversion from potential energy to kinetic energy. See also **Barotropic Disturbance**.

BAROCLINIC INSTABILITY. A hydrodynamic instability arising from the existence of a meridional temperature gradient (and hence vertical shear of the mean flow and a thermal wind) in an atmosphere in quasigeostrophic equilibrium and possessing static stability.

For reasonable values of the atmospheric parameters, the wavelength of maximum instability corresponds to that of a synoptic-scale disturbance. Such a system may be interpreted as converting potential energy of the basic flow into kinetic energy of the unstable perturbation.

AMS

BAROCLINIC MODEL. An atmospheric model that, in addition to the advection of the circulation field, includes thermal advection processes, an explicit representation of the thermodynamic energy equation, and at least two vertical data levels.

The inclusion of thermal advection processes, and in particular differential thermal advection between vertical levels, is essential to predict the development of new weather systems. Baroclinic models are the standard models used for making numerical weather forecasts by operational forecast centers.

BAROCLINITY. The state of stratification in a fluid in which surfaces of constant pressure (isobaric) intersect surfaces of constant density (isosteric). The number, per unit area, of isobaric–isosteric solenoids intersecting a given surface is a measure of the baroclinity. Also called *baroclinicity*, *barocliny*.

Barotropy is the state of zero baroclinity. Since the presence of solenoids (baroclinity) complicates the dynamics of the fluid, there has been much investigation of the extent to which an atmosphere, though obviously a baroclinic fluid, can be dynamically treated as barotropic.

BAROGRAPH. A barograph is a recording barometer. Barographs may be classified, on the basis of their construction, into the following types: 1) aneroid barograph (including microbarograph); 2) float barograph; 3) photographic barograph; and 4) weight barograph. The aneroid barograph is the one most commonly used in weather stations. See also **Aneroid Barograph**; and **Barometer**.

BAROMETER. An instrument for measuring atmospheric pressure. There are two types of barometers commonly used in meteorology: (1) The mercury barometer is basically a glass tube about 3 feet (1 meter) long, closed at one end, filled with mercury, and inverted with the open end immersed in a cistern of mercury. Mercury rises in the sealed tube above the level in the cistern in direct relation to the air pressure on the cistern surface. Numerous refinements are required in a mercury barometer before it is sufficiently accurate for precise pressure measurements. Two types are shown diagrammatically in Fig. 1. (2) The aneroid barometer consists of one or more thin corrugated hollow disks (aneroid capsules), which are partially evacuated of gas, and restrained from collapsing by an external or internal spring. The deflection of the spring will be nearly proportional to the difference between the internal and external pressures. Magnification of the spring deflection is obtained both by connecting capsules in series and by mechanical linkages. When one side of a disk is fixed, the other side will move and operate a system of levers, which, in turn, cause an indicator to move over a scale. If atmospheric pressure falls, the disk expands; if atmospheric pressure increases, the disk contracts. Aneroid barometers must be calibrated against a mercury barometer and checked frequently. See also **Altimetry**.

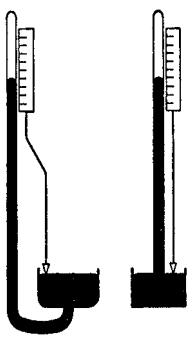

Fig. 1. Operating principle of two types of mercury barometer.

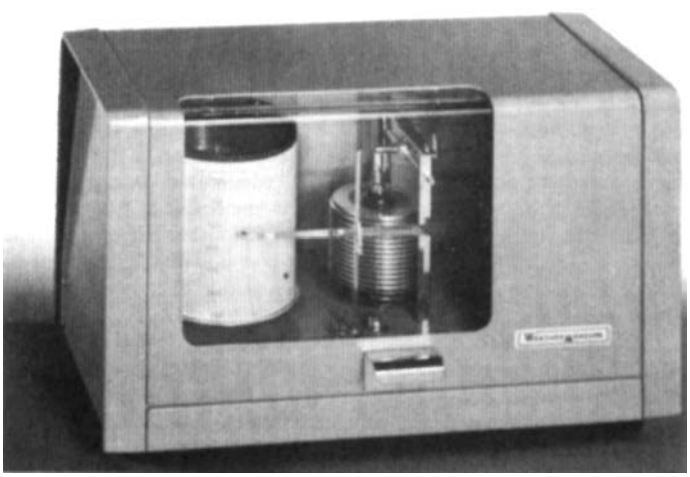

Fig. 2. Aneroid barograph. Pressure can be read directly under the pen. A time record is inked onto a chart affixed to a slowly revolving drum.

The weight barometer is a mercury barometer that measures atmospheric pressure by weighing the mercury in the column or the cistern. A siphon barometer is so constructed that the upper and lower mercury surfaces have the same diameter.

In meteorology, barometric tendency is defined as the changes of barometric pressure within a specified time (usually 3 hours) before a weather observation.

Barograph. In essence, an instrument that records barometric pressure — a recording barometer. The measurement principles are the same as the barometer, but in addition to an indicating pointer, a recording mechanism is added. An aneroid barograph is shown in Fig. 2.

BAROMETRIC CORRECTIONS. The corrections that must be applied to the reading of a mercury barometer in order that this observed value may be rendered accurate. There are four kinds. 1) The instrument correction is the mean difference between the readings of a given mercury barometer and those of a standard instrument. It is a composite correction, including the effects of capillarity, index misalignment, imperfect vacuum, and scale correction, which are the barometric errors. See also **Capillarity Correction**. 2) The temperature correction is applied to account for the difference between the coefficient of expansion of mercury and that of the scale. 3) The gravity correction is necessary because the acceleration of gravity varies with both altitude and latitude. 4) The removal correction is applied when the barometer elevation differs from the adopted station elevation and/or climatological station elevation. See also **Capacity Correction**.

BAROMETRIC EFFICIENCY. Water levels in wells are often observed to fluctuate as the air pressure changes. Blaise Pascal described this effect in 1663 and was the first to attribute the water level changes in wells to changes in atmospheric pressure. He noted that water levels declined as the barometric pressure increased, and vice versa.

The barometric efficiency, *BE*, is used to relate changes in water levels, ΔW, to changes in barometric (air) pressure, ΔB:

$$BE = -\frac{\Delta W}{\Delta B} \tag{1}$$

where consistent units (e.g., feet of water, mm of Hg, hPa) are used for both water levels and barometric pressure.

To understand why this relationship exists, we can conceive of an aquifer that is entirely isolated from the atmosphere. Such an aquifer maintains a constant total head, $H = H_o$, within the aquifer and is entirely unaffected by atmospheric pressure changes. Water level elevations, *W*, in the aquifer are measured in an open borehole.

The total head within the well is the sum of the water level elevation plus the barometric pressure exerted on the water surface, $H = W + B$. If the total head within the well is equal to the total head within the aquifer, $H_o = W + B$, and the total head within the aquifer is constant, then the water level varies inversely with barometric pressure, $W = H_o - B$.

The change in water level is just the negative of the change in barometric pressure, $\Delta W = \Delta(H_o - B) = -\Delta B$, so that the barometric efficiency is 100 percent, $BE = -\Delta W/\Delta B = -(-\Delta B)/\Delta B = 1$.

A second example assumes that the total head in the hypothetical aquifer increases with barometric pressure, $H = H_o + B$, so that the head in the aquifer goes up and down over time. In this case, the water levels in the well remain unchanged, and the barometric efficiency of the aquifer is zero.

These two extremes are shown in Fig. 1. Note that the barometric pressure is identical in both cases. In the left figure, the barometric efficiency is 100%, so that the water level varies inversely with barometric pressure. The total head is the sum of the barometric pressure and water levels, so it remains unchanged. In the right figure, the barometric efficiency is zero, so that the water level is unaffected by barometric pressure changes and the total head varies directly with barometric pressure.

Most aquifers lie between these two extremes, however, and the actual response depends, in large part, on whether the aquifer is confined or unconfined.

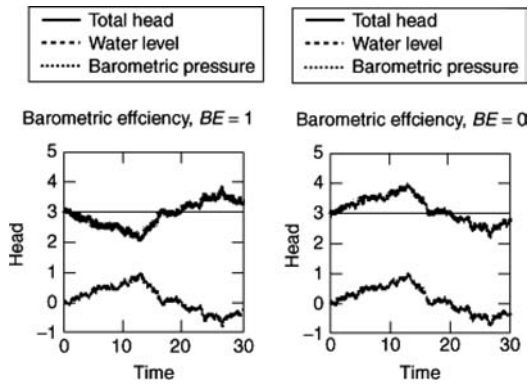

Fig. 1. Effect of barometric pressure on water levels in wells. Both figures show barometric pressure (lower, dashed line), total head (solid line), and water levels (dotted line). Left figure shows effects when the barometric efficiency is 100%, $BE = 1$, and right figure shows effects when the barometric efficiency is zero, $BE = 0$.

Confined Aquifers

For confined aquifers, Jacob showed that increasing the load on the ground surface increases the load on the aquifer. This additional weight is either carried by the mineral grains or by the water within the aquifer pores. If the entire weight is borne by the mineral grains, and these grains do not deform with the increase in load, then the total head within the aquifer remains unchanged, and the barometric efficiency is 100%.

The barometric efficiency is smaller if some of the weight is carried by the fluid. A very low barometric efficiency in confined aquifers occurs when the fluid within the aquifer bears most of the weight. Examples of such aquifers include poorly consolidated sedimentary aquifers or horizontal fractures that extend great distances.

Figure 2 shows the extreme conditions. In the left figure, the entire increase in load caused by an increase in barometric pressure is carried by the mineral grains. In this case, the pore fluids are not affected by the increase in load, the total head remains unchanged, and water levels drop in an amount equal to the increase in barometric pressure. In the right figure, the mineral grains do not carry the load and the fluid carries the increased load, causing an increase in total head.

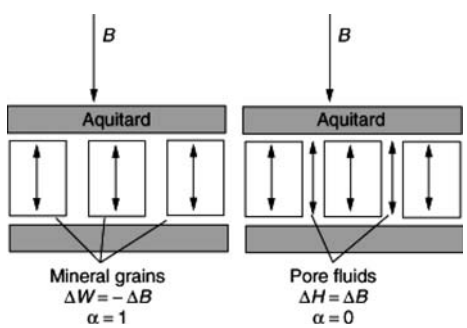

Fig. 2. Effect of barometric pressure on total head in confined aquifers. The mineral grains carry the load in the left figure, whereas the pore fluids carry the load in the right figure. Most confined aquifers, however, are intermediate between these two extremes.

In confined aquifers, the barometric response is virtually instantaneous. A change in barometric pressure should cause an immediate change in water levels in wells. Water levels in large-diameter wells may not respond immediately, however, because of the time required for water levels to adjust to the new level. Instead of a rapid response to pressure changes, a slow response may be found in these wells.

This phenomena is called *borehole storage* and is a function of the diameter of the borehole, the length of the screened interval relative to the aquifer thickness, the aquifer hydraulic properties (e.g., transmissivity and storativity), and the rate at which the barometric pressure is changing.

The effects of borehole storage can be eliminated by placing a packer in the well below the water surface, but above the screened interval, which eliminates the need for the water level to change in response to changes in barometric pressure. Some change in volume may result from the slight compressibility of water, but this effect is very small. A gauge-type pressure sensor (i.e., internally vented to the atmosphere) is then placed below the packer to measure the water pressure.

Several techniques are available for estimating the confined aquifer barometric efficiency, including linear regression and Clark's Method. Clark's method is an unbiased technique for estimating the barometric efficiency that performs well when a water level trend is present in the data. Regression provides a better estimate, but only when the trend function can be accurately specified.

Unconfined Aquifers

Barometric pressure changes commonly do not affect water levels in wells located in shallow, unconfined aquifers, which is because the air pressure moves rapidly through the unsaturated zone and causes an immediate increase in total head within the aquifer.

In deeper unconfined aquifers, however, the typical response to barometric pressure changes is to see an immediate inverse response (i.e., an increase in barometric pressure causes an equivalent and opposite water level response), followed by a slow decay back to the original water level.

To understand this complex response, we focus on how total head responds to barometric pressure changes. Initially, no increase in total head within the unconfined aquifer occurs because the water held within pores is not confined by an overlying confining unit. The total head within the aquifer can rise over time, however, as air diffuses downward through the unsaturated zone.

The total head in the unconfined aquifer increases once the air pressure change reaches the water table. The time required for the total head to respond to barometric pressure changes is a function of the depth of the water table and the air diffusivity within the unsaturated zone. The air diffusivity is higher in coarse, dry soils and is lower in wet soils or in soils with a low air permeability.

As the water level response in observation wells is the total head minus the barometric pressure, the fact that the total head does not change initially means that a rapid water-level response occurs to barometric pressure changes. In fact, the barometric efficiency is one in wells with a deep unsaturated zone — or where the air permeability of the unsaturated zone is low — followed by a gradual decrease as air diffuses downward to the water table.

This concept is illustrated graphically in Fig. 3. Note that the barometric pressure is simplified to a simple step change from zero to one. The total head does not initially respond, but slowly rises over time as the barometric pressure moves through the unsaturated zone and eventually reaches the water table. The observed water level in a well placed in this aquifer

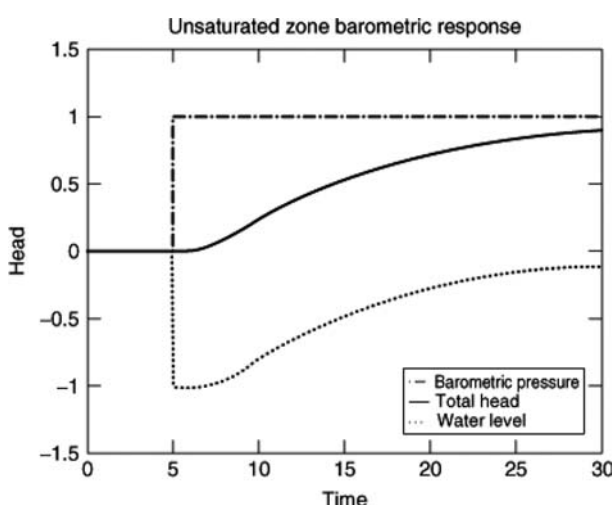

Fig. 3. Effect of barometric pressure on total head and water levels in confined aquifers. The barometric pressure in this example takes a step from zero to one at $t = 10$. The total head slowly rises as the barometric pressure makes its way through the unsaturated zone. The water levels initially fall to maintain the constant total head, but then return to normal once the barometric pressure signal reaches the water table.

responds immediately (as long as borehole storage can be neglected), but eventually decays back to its original level.

The barometric efficiency of unconfined aquifers is not single valued like the confined aquifer barometric efficiency. Instead, the response includes a delay that can be estimated using regression deconvolution. The resulting response can be used to estimate the unsaturated air diffusivity of the unsaturated zone.

BAROMETRIC PRESSURE. The pressure of the air at a particular point on or above the surface of the earth. At sea level, this pressure is sufficient to support a column of mercury approximately 29.9 inches in height (760 mm), equivalent to 14.7 lbs/inch^2 absolute (psia) or 1 atm.

BAROMETRY. The study of the measurement of atmospheric pressure, with particular reference to ascertaining and correcting the errors of the different types of barometer.

BAROMIL. The unit of length used in graduating a mercury barometer in the centimeter-gram-second system. If the barometer is located at 45° latitude at sea level and its temperature is 0 °C (32 °F), a length increment of one baromil will correspond to a pressure increment of one millibar. Corrections must be applied at other locations.

BAROSWITCH. (Or barometric switch.) A pressure-operated switching device used in a radiosonde. In operation, the expansion of an aneroid capsule causes an electrical contact to scan a radiosonde commutator composed of conductors separated by insulators. Each switching operation corresponds to a particular pressure level. The contact of an insulator or a conductor determines whether temperature, humidity, or reference signal will be transmitted.

BAROTROPIC. 1. That part of the velocity field that is either uniform with depth or has zero horizontal component of vorticity. In a purely barotropic flow, the pressure gradients and the density gradients are parallel so that their cross product, the baroclinic torque vector, is zero. Variations of fluid density are therefore not directly relevant to barotropic motion.

2. Of, pertaining to, or characterized by a condition of barotropy. See also **Barotropy**.

BAROTROPIC ATMOSPERE. A state of the atmosphere in which density depends only upon pressure, that is, a state such that surfaces of constant pressure and constant density coincide, so that the geostrophic wind is independent of height.

BAROTROPIC DISTURBANCE. (Or Barotropic Wave) 1. A wave disturbance in a two-dimensional flow, the driving mechanism for which lies in the variation of vorticity of the basic current and/or in the variation of the vorticity of the earth about the local vertical. Such wave disturbances are also known as Rossby waves. See also **Barotropic Instability**.

2. An atmospheric wave of cyclonic scale in which troughs and ridges are approximately vertical. See also **Baroclinic Disturbance**; and **Barotropy**.

BAROTROPIC INSTABILITY. The hydrodynamic instability arising from certain distributions of vorticity in a two-dimensional nondivergent flow. This is an inertial instability in that kinetic energy is the only form of energy transferred between current and perturbation. The variation of vorticity in the basic current may be concentrated in discontinuities of the horizontal wind shear (to be distinguished from Helmholtz instability, where the velocity itself is discontinuous) or may be continuously distributed in a curved velocity profile.

BAROTROPIC MODEL. 1. Any of a number of model atmospheres in which some of the following conditions exist throughout the motion: coincidence of pressure and temperature surfaces; absence of vertical wind shear; absence of vertical motions; absence of horizontal velocity divergence; and conservation of the vertical component of absolute vorticity. Barotropic models are usually divided into two classes: the nondivergent barotropic model and the divergent barotropic model (also called the *shallow-water equations*).

2. A single-parameter, single-level atmospheric model based solely on the advection of the initial circulation field. The simplest form of barotropic model is based on the barotropic vorticity advection equation:

$$\frac{\partial \nabla^2 \psi}{\partial t} + \mathbf{V}_\psi \cdot \nabla(\nabla^2 \psi + f) = 0$$

where ψ is the geostrophic streamfunction, $\mathbf{V}_\psi$ is the nondivergent wind, and f is the Coriolis parameter. The equation is derived by assuming that a vertical portion of the atmosphere is barotropic (i.e., density is constant on pressure surfaces) and nondivergent. Because there are no vertical variations or thermal advection processes in a barotropic model, it cannot predict the development of new weather systems.

BAROTROPIC VORTICITY EQUATION. The vorticity equation in the absence of horizontal divergence and vertical motion, so that the absolute vorticity of a parcel is materially conserved,

$$\frac{D}{D_t}(\zeta + f) = 0,$$

where ζ is the relative vorticity, and f the Coriolis parameter.

This equation may also be interpreted as governing vertically averaged flow in which divergence is present but wind direction is constant with height. See also **Equivalent Barotropic Model**; and **Vorticity Equation**.

BAROTROPY. The state of a fluid in which surfaces of constant density (or temperature) are coincident with surfaces of constant pressure; it is the state of zero baroclinity.

Mathematically, the equation of barotropy states that the gradients of the density and pressure fields are proportional:

$$\nabla \rho = B \nabla_p,$$

where is the density, p the pressure, and B a function of thermodynamic variables, called the coefficient of barotropy. With the equation of state, this relation determines the spatial distribution of all state parameters once these are specified on any surface. For a homogeneous atmosphere, $B = 0$; for an atmosphere with homogeneous potential temperature,

$$B = \frac{c_v}{c_p R T'}$$

where c_v and c_p are the specific heats at constant volume and pressure, respectively, R the gas constant, and T the Kelvin temperature; for an isothermal atmosphere, $B = 1/(RT)$. It is not necessary that a fluid that is barotropic at the moment will remain so, but the implication that it does often accompanies the assumption of barotropy. In this sense the assumption, or a modification thereof, is widely applied in dynamic meteorology. The important consequences are that absolute vorticity is conserved (to the extent that the motion is two dimensional), and that the geostrophic wind has no shear with height. See also **Barotropic Vorticity Equation**; **Barotrophic Instability**; **Barotropic Disturbance**; and **Equivalent Barotropic Model**.

BARRACUDA *(Osteichthyes)*. Of the suborder *Sphyraenoidei* and family *Sphyraenidae*, barracudas are excellent swimmers. They are chiefly found close to tropical sea coasts. From there, they migrate extensively during the summer months as far as northern or southern temperate seas. They pursue schooling fishes. The body is elongated, pike-like, and is covered with small cycloid scales. The head is very long and tapered, with a protruding lower jaw. The mouth is horizontal and can open very wide. The teeth are on the jaws and the palatine bone; they are larger in front and in the very front, barracudas have powerful grasping teeth. Like mullet, the dorsal fins are widely separated; the first dorsal fin has five strong spines. The caudal fin is forked. There is just one genus, *Sphyraena*, with 18 species.

Divers in tropical regions fear the attacks of the sometimes-giant barracudas more than they fear sharks. As observed by Herald and Vogt, "Barracudas are incalculable. Although they do not sneak up on divers, they follow them everywhere. Since they perceive prey less through smell than through sight, they orient to everything which catches their attention, either through colors or unusual movements, such as those of an injured fish. Unlike shark, barracudas undertake just a single attack, and in attacking they leave wounds which are not torn out at the edges."

The life habits of the Pacific barracuda (*Sphyraena argentea*) are the best understood of any barracuda. This species winters off Mexico and, in spring, schools of them move up the coast to spawn. The spawning season extends from April to September. The eggs are laid at intervals and float in the water. Males attain sexual maturity in their second or third year, while females require an additional year. Barracuda diet consists chiefly of sardines. The Pacific barracuda can attain a length up to nearly 5 feet (1.5 meters). These barracudas are caught off Mexico throughout the year, and off California only in summer. The meat is considered very flavorful and is quite firm.

Other barracudas grow to be much larger. The Indo-Malaysian barracuda (*S. jello*) can reach a length up to 10 feet (3 meters). The great barracuda (*S. barracuda*) achieves equally great lengths. See Fig. 1 on p. 378. The European barracuda (*S. sphyraena*) grows to about 3 feet (1 meter) in length and allegedly attacks bathers on occasion. It is considered a good market species. The southern sennet (*S. picudilla*) attains a length of about 18 inches (45 centimeters). Its habitat is the west Atlantic Ocean from the Bermudas to Brazil.

See entry on **Fishes**, which includes a list of references at the end of the entry.

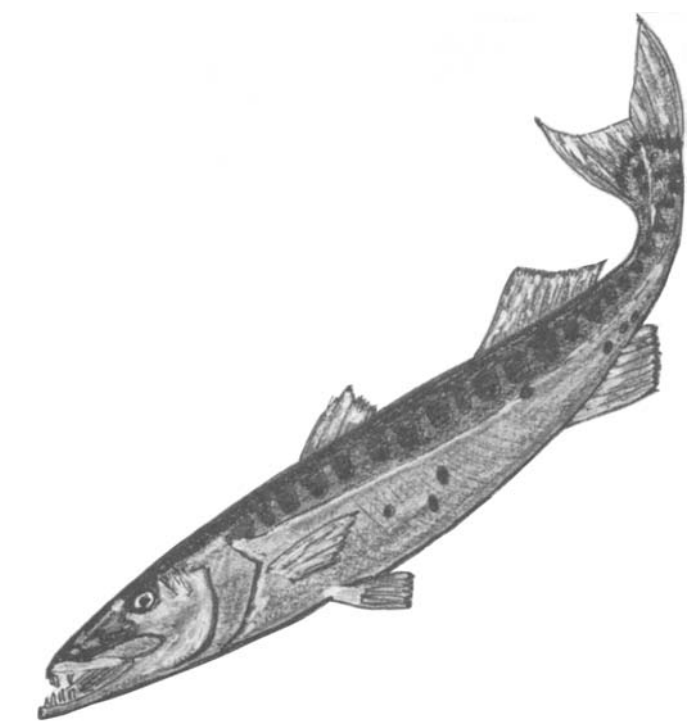

Fig. 1. Great barracuda (*Sphyraena barracuda*).

BARRANCO. A deep, normally rock-walled ravine with steep sides. The term also is used to describe a gorge, small canyon, or deep cleft, gully, arroyo, or other break made by a heavy rain.

BARRIER BEACH. A single, narrow, elongate and ridge rising slightly above the high-tide level and extending generally parallel with the shore, but separated from it by a lagoon or marsh. A barrier beach is extended by longshore drifting and is rarely more than several kilometers long. Also, sometimes called an *offshore barrier*.

BARRIER JET. A jet on the windward side of a mountain barrier, blowing parallel to the barrier. The jet is produced when stable synoptic flow at low levels approaches the barrier and is blocked (see **Blocking**) for a significant fraction of a day or longer. This often occurs, for example, when a cold front approaches the barrier. The component of the large-scale flow perpendicular to the ridge forces the flow to ascend the barrier. Because the air column is stable, the air layer near the surface is potentially colder (by definition) than the air layer above it and the stratification opposes and retards the upslope flow. As the colder air ascends, it produces higher pressure along the slope than at the same level over the plain, and consequently also a pressure-gradient force directed away from the mountains. If this pressure configuration lasts for several hours or more, Coriolis deflection accelerates the flow with a component perpendicular to the pressure gradient, that is, in the along-barrier direction. At timescales greater than a pendulum day — that required for geostrophic adjustment — these processes produce a persistent barrier jet at heights below the level of the mountain. The process of geostrophic adjustment also brings the flow in the jet into balance with the thermal wind, so an argument based on thermal wind reasoning also explains the barrier jet. Barrier jets have been documented windward of the Sierra Nevada in California, to the north of the Brooks Range in Alaska, and in Antarctica along the Antarctic Peninsula and the Transantarctic Mountains. Maximum speeds, which generally occur at heights just below the midway level of the mountains, reach 15–30 m s^{-1}, and the jet can extend laterally 100 km (62 miles) or more upstream of the barrier. The strong shear in the jet is capable of producing moderate to severe turbulence for low-flying aircraft. See also **Winds and Air Movement**.

BARRIER LAYER. 1. An electrical double layer formed at the junction, or surface of contact, between a metal and a semiconductor, or between two metals, for various purposes.

2. The depth range, where it exists, between the bottom of the oceanic surface mixed layer and the thermocline, usually at a depth between 30 and 80 meters (98 and 262 feet). The barrier layer is found in tropical regions where the mixed layer contains water of lower salinity than but identical in temperature to that of the water below. Its significance is that it acts as a barrier to the vertical penetration of heat into the ocean because, without a temperature gradient at the bottom of the mixed layer, entrainment of water from below does not remove any heat from the mixed layer.

BARRIER LAYER CELL. The barrier layer cell is a photoelectric device that produces a small electromotive force upon the incidence of light or other radiant energy upon its barrier layer or junction.

BARRIER *(Moisture)*. Any substance that is impervious to water or water vapor. Most effective are high-polymer materials such as vulcanized rubber, phenolformaldehyde resins, poly(vinyl chloride), and polyethylene, which are widely used as packaging films. The chief factors involved are polarity, crystallinity, and degree of cross-linking. Water-soluble surfactants and protective colloids increase the susceptibility of a film to water penetration. Any pigments and fillers must be completely wetted by the polymer. Properly formulated paints are effective moisture barriers.

BARRIER REEF. A narrow and long coral reef essentially parallel with the shore. The reef usually is separated from other land by a lagoon of considerable depth and width. Typically, a barrier reef will enclose much or all of a volcanic island. In the case of the Great Barrier Reef that lies off the coast of Queensland, Australia, it is a considerable distance from the continental coast. See also **Coral Reef**.

BARTON, DEREK H. R. (1918–1998). An English organic chemist who won the Nobel Prize for chemistry in 1969 with Odd Hassel. The field of conformational analysis in organic chemistry was initiated through his research in the terpene and steroid fields. He did extensive research

in the area of carbanion autoxidations. He was instrumental in research concerning the relationship of molecular rotation to structure in complex organic molecules. His education took place in London, France, and Ireland.

BARYCENTRIC PARALLAX. A term given to a slight oscillatory motion of the earth. The center of gravity of the earth-moon system revolves about the sun in an orbit that is usually referred to as the orbit of the earth. Both the earth and moon are revolving about this center of gravity of the system as it, in turn, revolves about the sun. At the time of conjunction of the moon with the sun, the moon is inside the orbit of the system about the sun, and the center of the earth is outside. At opposition, this condition is reversed, and the center of the earth is on the inside. Hence, the center of the earth oscillates slightly back and forth across the orbit within a period of one synodic month. It is this slight oscillatory motion of the earth that is known as barycentric parallax.

Accurate measurements of barycentric parallax provide a method for the determination of the relative masses of the earth and the moon. In accordance with the principles of mechanical equilibrium, the distances between the center of gravity of the earth-moon system and the centers of mass of the two individual objects are inversely proportional to the masses of the objects. Hence, if we can determine the distance of this center of mass of the system from the centers of the earth and moon, we can at once determine the relative masses of the two objects. Accurate measurements of barycentric parallax determine the position of the center of mass of the earth-moon system as being 4,600 kilometers from the center of the earth.

See also **Moon (Earth's)**.

BARYE. The pressure unit of the centimeter-gram-second system of physical units; equal to one dyne per cm^2 (0.001 millibar).

BARYONS. A class of subatomic particles including the proton, the neutron, and several heavier particles, such as the lambda, the sigma (plus, minus, and neutral), and the omega (minus) particles. Baryons are particles that interact with the strong nuclear force. Each baryon is given a baryon number 1, each corresponding antibaryon is given a baryon number −1, while the light particles (photons, electrons, neutrinos, muons, and mesons) are given baryon number 0. The total baryon number in a given reaction is found by algebraically adding up the baryon numbers of the particles entering into the reaction. During any reaction among particles, the baryon number cannot change. This rule ensures that a proton cannot change into an electron, even though a neutron can change into a proton. Similarly, to create an antiproton in a reaction, one must simultaneously create a proton or other baryon. Baryon conservation ensures the stability of the proton against decaying into a particle of smaller mass. See also **Conservation Laws and Symmetry**; **Neutron**; **Particles (Subatomic)**; and **Proton**.

BARYTOCALCITE. This mineral is a carbonate of barium and calcium; it crystallizes in the monoclinic system but occurs massive as well. It has a perfect cleavage parallel to the prism and one, less perfect, parallel to the base; fracture, sub-conchoidal; brittle; hardness, 4; specific gravity, 3.66–3.71; luster, vitreous; color, white or gray or may be greenish or yellowish; transparent to translucent. Barytocalcite is found in Cumberland, England, associated with barite and fluorite.

BASAL CELL NEVUS SYNDROME. An inherited condition characterized by multiple defects of the eyes, skin, nervous system, endocrine glands, and bones. Children with the disease often have wide-set eyes, a broad bridge of the nose, a heavy ridge over the eyes, and a protruding jaw. The disorder is also characterized by multiple basal cell skin cancers that are frequently located around the eyes, upper lip, and cheek bones. These are the same types of skin cancers caused by overexposure to the sun.

Basal cell nevus syndrome is inherited as an autosomal dominant trait, meaning that if one parent has the disease, there is a 50% chance that the disease will pass to a child. At least one parent must be affected in order for the child to inherit the disease.

In addition to the characteristic facial appearance and the predisposition for skin cancers, symptoms may include mental retardation, seizures, brain tumors, spontaneous bone fractures, and deafness. Pits are sometimes visible in the palms of the hand and soles of the feet. Abnormal tooth development can result from cysts in the upper and lower jaws. Other bone defects associated with the disease include scoliosis (curvature of the spine), kyphosis (severe rounding of the upper back), and rib abnormalities.

Other symptoms of the disease in the eyes may include defects of the iris, irregular pupils, cataracts, and blindness.

To properly diagnose basal cell nevus syndrome, physicians will biopsy tumors to determine if they are basal cell carcinomas. X-rays will also be performed to determine the type and extent of bone defects and whether there are mineral deposits in the brain or other tissues. An eye care professional will examine the patient's eye for signs of cataracts, pupil abnormalities, and defects of the iris.

Several different specialists are usually involved in treating the disorders: ophthalmologists for the eye problems, oncologists for the tumors, orthopedists for the bone abnormalities, and so on. The outcome will vary according to the severity of the symptoms and associated complications.

Prospective parents with a family history of basal cell nevus syndrome should undergo genetic counselling because there is a 50% probability that an infant will be affected if one parent is affected.

Vision Rx, Inc., Elmsford, NY

BASAL CONGLOMERATE. A conglomerate that lies on, or occurs just above, a plane of erosion or unconformity. Such a conglomerate constitutes the first sedimentary stage in a normal cycle of sedimentation.

BASAL METABOLISM. The metabolism of a living cell or organism refers to the total turnover of chemical material and energy. It consists of *anabolism*, or assimilation, mostly of substances of high potential energy (primarily protein, fat, and carbohydrate), and *catabolism* or dissimilation. In common speech, metabolism refers to the oxidation of major foodstuffs and the concomitant release of energy. Metabolic rate refers to the metabolism in a given period of time. The "basal" metabolic rate refers to the fundamental energy requirement for maintenance and continued functioning of the organism (aside from external muscular work and work of digestion), such as respiration, contraction of the heart, function of the kidney, the liver, and of all cells in general. Basal metabolic rate (BMR) in humans refers to the determination of metabolic rate under certain standardized conditions, including complete physical rest (but not sleep), a fasting state, and an ambient temperature that does not require energy expenditure for physiological temperature regulation. Actually the BMR refers not to a "basal" rate but to a determination under these standard conditions. The BMR is below normal in sleep, starvation, anesthesia, and certain endocrine disturbances (hypothyroidism), and is elevated in fever, athletic training, under the influence of drugs (e.g., caffeine) and endocrines (adrenaline, thyroid hormones).

In studies of animals it becomes technically difficult to make observations under standard conditions which include rest. Restraining an animal increases the metabolic rate and inactivation through anesthesia lowers it; ruminants and other plant eaters cannot be brought into a fasting state unless they are deprived of food for prolonged periods of time; small animals (e.g., shrews) have such high metabolic rates that they must eat almost continuously to sustain a normal metabolic rate, etc.

Methods of Determination. In principle, the metabolic rate is determined in three different ways. (a) Determination of the energy value of all food less the energy value of excreta (mainly feces and urine) should give the energy turnover of the organism. However, the result must be corrected for any change in the composition of the body, mainly deposition or utilization of body fats. The method is cumbersome and is accurate only if the period of observation is sufficiently long. (b) Measurement of total heat production of the organism. This is fundamentally the most accurate method. The value obtained must be corrected for any external work performed, including such items as heating of the foodstuffs taken in, vaporization of water, etc. The determinations are made with the organism in a calorimeter, technically a rather difficult procedure, but it yields very accurate results. (c) The amount of oxygen used in oxidation processes can be used to determine the metabolic rate. (In theory, the carbon dioxide production could also be used, but it is less accurate, mainly because there is a large pool of carbon dioxide in the organism that undergoes changes relatively easily.) The reason that oxygen can be used is that similar amounts of heat are produced for each liter of oxygen, irrespective of whether fat, carbohydrate or protein is oxidized. The figures are: fat 4.7 kcal; carbohydrate, 5.0 kcal; and protein, 4.5 kcal, per liter oxygen. It is customary to use an average value, 4.8 kcal/liter oxygen consumed. The use of oxygen consumption for the determination of metabolic rate is so common that the two concepts have become practically synonymous.

Obviously, the oxygen consumption cannot be used for determinations of metabolic rate in, for example, anaerobic organisms.

Temperature Effects. Animals whose body temperature changes with that of the environment (poikilothermic or cold-blooded animals) have a metabolic rate which depends on their temperature. In general, the metabolic rate increases, within the range tolerated by the organism, some two- or threefold for a temperature increase of 10 °C. This change, designated as Q_{10}, is a term preferred by most physiologists and biologists over the use of the Arrhenius constant, which is a thermodynamically more correct way of expressing temperature dependence. Because of the temperature effect, information about metabolic rate in cold-blooded animals is meaningful only if the temperature is known.

Mammals and birds maintain a relatively constant body temperature within a wide range of ambient temperatures, and are called warm-blooded or homothermic animals. When the ambient temperature falls below a certain critical level, their metabolic rate increases so that the increased heat loss is balanced by increased heat production. Most of the increased heat production is due to involuntary muscle contractions (shivering).

Metabolic Rate in Relation to Body Size. If a uniform group of animals, such as mammals, is used for a comparison of metabolic rates, an interesting relationship is revealed. The smaller the animal, the higher is the metabolic rate per gram of body weight. If, on logarithmic coordinates, the metabolic rate is plotted against body size, we obtain a straight line (see Fig. 1) that corresponds to the equation: log metabolic rate $= k + 0.74$ log body weight (k being a constant whose numerical value depends on the units used). It has been suggested that this relationship expresses the need for a higher heat production in the smaller animal, which, because of its larger relative surface, must produce heat at a higher rate than a large animal in order to maintain its body temperature. However, similar relationships between metabolic rate and body size have been found in numerous groups of cold-blooded animals as well as plants, where the need for heat regulation cannot be the fundamental explanation of this interesting relationship.

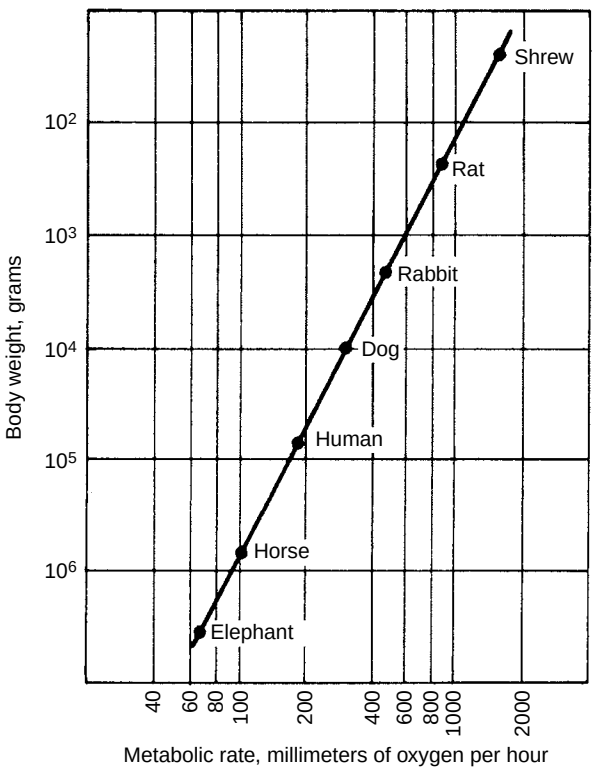

Fig. 1. Body weight versus metabolic rate plotted on logarithmic coordinates.

BASAL PLANE. The plane normal to the principal axis, or "c" axis, in hexagonal or tetragonal crystals.

BASALT. A fine-grained to dense, sometimes porphyritic, intrusive or extrusive igneous rock, black or greenish-black in color, characterized by a preponderance of calcic plagioclase feldspars and pyroxene together with minor amounts of accessory minerals such as olivine. Glass may be present. Amygdaloidal structure is common in such cavities and beautifully crystallized species of zeolites, quartz or calcite are frequently found.

The lava flows of the Plateau of the Deccan in India, the Columbia Plateau of Washington and Oregon States, as well as the Triassic lavas of eastern North America are basalts. Perhaps the most famous basalt flow in the world is the Giants Causeway on the northern coast of Ireland, in which the vertical joints give the impression of having been artificially constructed. Pliny used the word basalt and it is said to have had an Ethiopian origin, meaning a black stone.

BASE (Chemistry). See **Acids and Bases**.

BASE LEVEL. The ultimate physiographic feature of the processes of denudation is the reduction of the land surface to sea level, because it is at this level that the processes of river erosion cease. As sea level is the datum plane below which stream erosion is impossible this may be taken as the theoretical lower limit of stream erosion and the level to which all the land surfaces must be brought if no other forces intervene. Actually, however, base level seems to be a limit which, however closely approached, may not in reality ever be reached. Therefore, a broader use of the term base level is frequently made, base level being the lowest level to which a given stream can cut. A stream flowing into a body of water at an elevation above the ultimate datum, sea level, is said to be at a temporary base level. In any case when a stream has cut its channel to such a degree that it has just enough velocity to carry its load without further erosion being possible, it is then said to be at grade. Local or temporary base levels of relatively small area may be developed without reference to sea level. In this sense the term base level is not entirely comparable to the term peneplain.

BASE LINE. (a) A surveyed line on the earth's surface or in space, whose exact length and position have been accurately determined with more than usual care, and that serves as the origin for computing the distances and relative positions of reference to which surveys are coordinated and correlated. (b) The initial measurement in triangulation, being an accurately measured distance constituting one side of a series of connected triangles and used, together with measured angles, in computing the lengths of the other sides. (c) One of a pair of coordinated axes (along with the principal meridian) used in the United States Public Land Survey system, consisting of a line extending east and west along the true parallel of latitude passing through the initial point and along which standard township, section, and quarter-section corners are established. The base line is the line from which the survey of the meridional township boundaries and section lines is initiated and from which the townships, either north or south, are numbered. (d) An aeromagnetic profile flown at least twice in opposite directions and at the same level, in order to establish a line of reference of magnetic intensities on which to base an aeromagnetic survey. (e) The center line of location of a railway or highway; the reference line for the construction of a bridge or other engineering structure. Sometimes spelled *baseline*.

American Geological Institute, by permission

BASE MAP. See **Meteorology**.

BASE PERIOD. In statistics, the period of time for which data used as the base of an index-number, or other ratio, have been collected. This period is frequently one of a year, but it may be as short as one day or as long as a run of years. The length of the base period is governed by the nature of the material under review, the purpose for which the index-number (or ratio) is being compiled and the desire to use a period as free as possible from abnormal influences in order to avoid bias.

BASE POINT. In computer terminology, the character, or the location of an implied symbol, which separates the integral part of an expression in positional notation from the fractional part; the point which marks the place between the zero and negative powers of the base. Also called *radix point*. See also **Binary Number**; **Fixed-Point Arithmetic (Computer System)**; and **Floating-Point Arithmetic**.

BASE PRESSURE. In aerodynamics, the pressure exerted on the base, or extreme aft end, of a body, as of a cylindrical or boattailed body or of a blunt-trailing-edge wing, in a fluid flow.

BASIC OXIDE. An oxide that is a base or that forms a hydroxide when combined with water and/or that will neutralize acidic substances. Basic oxides are all metallic oxides, but there is a great variation in the degree of basicity. Some basic oxides, such as those of sodium, calcium, and magnesium, combine with water vigorously or with relative ease and also neutralize all acidic substances rapidly and completely. The oxides of the heavy metals are only weakly basic, do not dissolve or react with water to any extent, and neutralize only the more strongly acidic substances. There is a gradual transition from basic to acidic oxides, and certain oxides, such as aluminum oxide, show both acidic and basic properties.

See also **Acids and Bases**.

BASIC ROCK. A term applied to igneous rocks whose content of silica is less than about 52%. It is not an exact term and is gradually going out of use. It may be convenient for field use.

BASIC SALT. A compound belonging to the categories of both salts and bases, because it contains OH (hydroxyl) or O (oxide) as well as the usual positive and negative radicals of normal salts. Among the best examples are bismuth subnitrate, often written $BiONO_3$; and basic copper carbonate, $Cu_2(OH)_2CO_3$. Most basic salts are insoluble in water and many are of variable composition.

BASIC SOLVENT. A solvent that accepts protons (hydrogen ions) from the solute.

BASIDIOMYCETES. Nearly all the fungi commonly observed belong to this group, which includes toadstools, mushrooms, puff-balls, and many other forms. The characteristic feature that distinguishes them from other fungi is the basidium, typically a club-shaped structure bearing four spores at its apex. Members of this group are found wherever plant life can exist. The majority of them are saprophytes, living on dead wood and soil rich in humus; a few are parasites. The life-history of the common mushroom, one of the best known and most important, is fairly typical of the group. See Fig. 1.

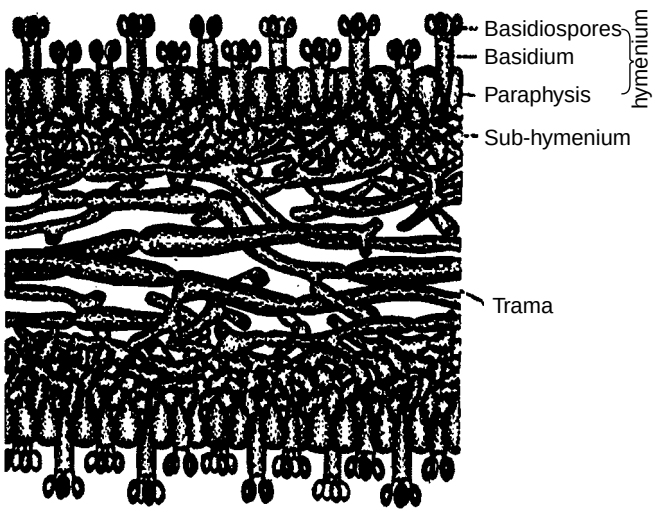

Fig. 1. A section through the gill of a mushroom (*Coprinus comatus*). Section cut perpendicular to the surface of the gill. (*Buller, "Researches on Fungi," Longmans, Green & Co.*)

The vegetative phase consists of a mycelium. This is a mass of slender much-branched threads, called hyphae, which grow throughout the substratum. The mycelium is perennial. Each hypha is a long filament composed of many segments, each containing two nuclei. The hyphae absorb from the substrate the organic materials the fungus needs in order to live, and convert it into other forms. Much of this food substance accumulates within the mycelium.

When sufficient material has been stored and conditions are suitable, the fungus fruits. The fruit body first appears as a small round object rising from the substratum. This elongates into a stalk bearing at its tip an umbrella-shaped cap or pileus.

On the lower surface of the pileus there are numerous thin radiating plates called gills. The lateral surfaces of the gills are formed by hyphal tips, which grow perpendicular to the surface and form a compact layer called the hymenium. The hyphal tips composing the hymenium are the basidia, the reproductive structures which distinguish this group of fungi from all others. Each basidium is a cylindrical, binucleate body cut off from the tip of a hypha. The two nuclei fuse and immediately divide, usually twice, so that the basidium contains four haploid nuclei. From the outer end of the basidium four slender pegs called sterigmata develop. A small spore forms at the tip of each sterigma. Into each spore one of the nuclei of the basidium migrates. The spore is discharged from the sterigma and falls down between the gills and into the air. It is carried about by air currents and eventually falls to the ground. There the spore germinates, giving rise to a slender branching mycelium composed of uninucleate segments. This is the primary mycelium. Branches of two primary mycelia unite to form a secondary mycelium. The two nuclei present in each segment of a secondary mycelium have come from different spores. The manner in which they continue their identity during division is interesting. The two nuclei divide simultaneously. When division is about to occur a small bulge forms on the side of the hypha. See Fig. 2. One of the two nuclei enters this bulge, the other remains in the hypha. After division a cross wall forms, separating the two nuclei in the hypha. The protuberance containing the other nucleus continues to grow and forms an elbow-shaped structure, which joins the two cells of the hypha. It is called a clamp connection. One of the nuclei formed in this clamp returns to the original cell, the other passes through the clamp and into the other cell. By this means the two cells each receive a nucleus derived from one of the original nuclei. Nuclear fusion occurs only in the basidium. So there is in the mushroom an alternation of generations differing from that in most plants. The haploid or gametophyte phase consists of the primary mycelia. Following this, a prolonged binucleate or dikaryon phase exists. Only in the basidium does nuclear fusion occur and reduction immediately follows. So the diploid phase or sporophyte is represented only by the basidium. There are no sex organs in this group of plants. The difference between the edible mushroom and other basidiomycetes is mainly in the structure of the fruit body, the location of the hymenium and the nature of the basidia.

The nature of the hymenium is the basis for classifying basidiomycetes. The Hymenomycetes are those in which the hymenium is exposed; in the Gasteromycetes it is formed within the fruit body. The principal order of Hymenomycetes is the *Agaricales* or agarics, or the gill fungi.

Fig. 2. A mushroom. (*A.M. Winchester*.)

Another well-known order of basidiomycetes is the *Polyporales*; of these the polypores or Polyporaceae are best known. The distinguishing features of these are the pits or tubes on the lower surface of the fruit body. The hymenium lines these pits. The fruit bodies of the polypores usually do not have a stalk and pileus, but form a layer spreading over the surface of rotting wood or grow out from the wood like a shelf. This shelf-like habit has given to these plants the name bracket-fungi. The fruit bodies of bracket-fungi live for many years and often show distinct growth layers.

The other large group of basidiomycetes is the Gasteromycetes, distinguished by having the hymenium lining irregular cavities in the fruit body. Until these are fully mature, the spore-bearing parts are completely enclosed by sterile tissue. These are many different kinds of Gasteromycetes. One of the best known is the puff-balls, or Lycoperdiales. The outer wall or peridium of the puff-ball surrounds the gleba or spore-bearing tissues. When the spores are mature the peridium breaks. In some genera the wall breaks up into irregular fragments and leaves the spore-mass exposed; in others a pore is formed at the apex of the fruit body. The slightest pressure against the peridium will cause clouds of spores to puff from the pore. The number of spores formed in a single puff-ball is tremendous; 7,000,000 has been given as the number from a good-sized sporophore. Some of the puff-balls are the largest fungi known, reaching a diameter of 12 inches (30 centimeters) or more. If gathered before the spores are formed, most of the puff-balls are edible. None are poisonous.

Geasters or earth-stars develop very much as puff-balls do. But when they are mature, the outer peridium splits into sectors, which bend outward, revealing the spore-bearing part within. These fungi are frequently found growing on dry sandy soil.

Another group of Gasteromycetes includes the Bird's-nest fungi. The spore-bearing structures here are the "eggs," small oval bodies resting in the bottom of an open cup of sterile tissue. A last and curious group of Gasteromycetes is the stinkhorns, vile-smelling fungi whose spores are included in a mass of sticky stinking tissue, formed by the disintegrated glebal substance. This attracts carrion flies and other insects, which carry the spores about.

Other important families of basidiomycetes are the rusts and the smuts. See also **Foodborne Diseases**; **Fungus**; and **Rust Fungi**.

There are several theories as to the origin of the basidiomycetes. Some maintain that they have evolved directly from certain primitive flagellates. Others derive them from the red algae. Many consider them to have descended from the ascomycetes. Adherents to this theory observe the dikaryon phase of the ascogenous hypha of the ascomycetes and note that if this phase were prolonged for some time it would be very similar to the secondary mycelium of the basidiomycete. They also note that the sexual reproduction by conidia occurs in the basidiomycetes very much as it does in the ascomycetes. See **Ascomycetes (Sac Fungi; Fungi)**.

The basidiomycetes include many important plants. Many are much sought as food. A few, and especially the field mushroom, *Agaricus campestris*, shown in Fig. 3, are extensively cultivated. See **Agarics**.

Many basidiomycetes are serious disease-producing plants, attacking trees particularly. Often their presence is unnoticed until too late; the mycelium has permeated the tissues of the host. Other basidiomycetes attack dead plants, reducing them to simpler forms. These are the basidiomycetes which cause decay. They are saprophytes.

BASILAR MEMBRANE. A membranous partition in the auditory chamber (cochlea) of the inner ear forming the floor of the cochlear duct. Upon it lies the organ of Corti, which contains the sensory cells for hearing. The basilar membrane increases in width as it passes from the base of the cochlea toward the apex, thus influencing the character of the vibrations with which the basilar membrane responds to sounds of different frequency. See also **Hearing and the Ear**.

BASILISK *(Reptilia, Sauria. Basiliscus).* A large tropical American lizard with crests on the back and tail that resemble the fins of fishes. Four species are known.

BASIL (Sweet Basil). See **Spices**.

BASIN. In structural geology, a special type of folded structure in which the strata dip in toward a central point from all directions. As exposed at the surface the ground plan of a basin may be roughly circular or elliptical. Type locality, the Paris Basin, France.

BASOMMATOPHORA. An order of snails with eyes located at the bases of the tentacles.

BASS (Acoustics). Those frequencies at the lower end of the audible range. A bass control is a tone control having the ability to increase or decrease the bass frequency gain of an audio amplifier. A bass compensator is an equalizer used to correct the bass response of an audio amplifier system. A bass reflex is a baffle for loudspeakers which employs a tuned port or opening which returns the sound from the rear of the speaker in an additive phase. Thus, the sound output is enhanced over a certain range of frequencies. See **Acoustics**.

BASS *(Osteichthyes).* All bass are of the order *Percomorphi*. Sea bass, along with groupers, are of the family *Serranidae*, of which there are approximately 400 species. They are among the most important food fishes. Most species of bass are marine. A few inhabit brackish and fresh water. The American white and yellow bass are strictly fresh water fishes.

Sometimes called jewfishes, giant sea bass have been recorded with weights up to 800 pounds (233 kilograms). Sport fishermen's tackle records are considerably lower: 513 pounds (408 kilograms) (7 feet, 2 inches; 2.2 meters) for the *Stereolepis gigas* (California species) and 551 pounds (250 kilograms) (8 feet, 4 inches; 2.5 meters) for the Atlantic *Epinephelus itajara*. Originally, the striped bass (*Roccus saxatilus*) was found in waters along the American Atlantic coast from the Gulf of St. Lawrence to northern Florida. Two shipments of some 400 fish were moved to California where they were placed in the San Francisco area. The population exploded at such a rate that a commercial fishery for them was established only ten years later. The fish now occurs on the American West coast all the way from northern Washington to southern California. For spawning, the stripers seek fresh water. A mature female at the age of 5 years attains a length of about 2 feet (0.6 meter). Males mature earlier (2 years) and are smaller (average length of 1 foot). Records indicate the

largest of the stripers to be caught was at Edenton, North Carolina (125 pounds; 57 kilograms). The largest on record on the West coast is 73 pounds (33 kilograms).

Two other species of striped bass inhabit fresh waters, mostly in the eastern United States: (1) *Roccus mississippiensis*, which has a characteristic yellow coloration of the body; and (2) *Roccus chrysops*, the white bass. Both fishes reach a length of about 18 inches (46 centimeters). Another species, *Roccus americanus*, a 12-inch (30-centimeter) perch (no stripes on side of body) originally inhabited the waters of the American Atlantic seaboard, later migrating inland.

The large-mouth bass (*Micropterus salmoides*) is a member of the family of sunfishes (*Centrarchidae*) and is one of the better known of American fresh water sporting fishes. Records indicate the largest specimen to be about $22\frac{1}{2}$ pounds (10.2 kilograms) ($32\frac{1}{2}$ inches (82 centimeters) long). The small-mouth bass (*Micropterus dolomieui*) has been recorded at 12 pounds (5.4 kilograms) (27 inches (68 centimeters) long). Both of these larger members of the centrarchids frequently feed upon smaller sunfishes. It is, therefore, usual stocking practice to include these smaller forage fishes, such as the common bluegill (*Lepomis macrochirus*) when introducing the larger bass.

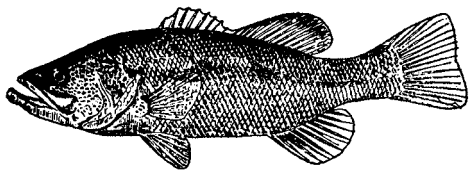

Fig. 1. Large-mouth black bass.

The large-mouth black bass (*Micropterus* [*Huro*] *salmoides*) is shown in Fig. 1. This fish inhabits fresh water in the eastern United States from the Great Lakes region south into Mexico. The fish has been widely introduced throughout North America, Europe, and other parts of the world.

See also **Fishes**.

BASSWOOD TREES. Known as basswoods in North America, as lindens in Germany, as tilleuls in France, and as limes in Britain, these trees are of the family *Tiliaceae* (basswood or linden or lime family). See Fig. 1. There are several species and hybrids of interest. Generally these trees may be characterized as deciduous, favoring sun but tolerant of some shade, capable of fast growth, alternate-growing, toothed leaves, and fragrant, creamy-white but small flowers occurring in drooping clusters which are pendent from a leaf-like bract. Although all species cannot be described here in detail, the more important species include:

American basswood (or American lime or linden)	*Tilia americana*
Big-leafed linden (or big-leafed lime)	*T. platyphyllos*
Chinese linden	*T. henryana*
Crimean linden	*T. X euchlora*
Downy basswood	*T. michauxii*
European linden (or common lime)	*T. X europaea*
Korean lime	*T. insularis*
Red-twigged lime	*T. platyphyllos* "Rubra"
Shrubby lime	*T. kiusiana*
Siberian lime	*T. mandshurica*
Silver linden (or silver lime)	*T. tomentosa*
Small-leaved linden (or small-leaved lime)	*T. cordata*
Weeping silver lime (or pendant silver linden)	*T. petiolaris*
White basswood	*T. heterophylla*

The American basswood is native to the Midwestern United States and Canada, ranging from New Brunswick in the northeast to Manitoba and the Dakotas in the west and southward into Nebraska, Oklahoma, and Kansas. It is also found in eastern Texas and in the mountains in Virginia, Georgia, and the Carolinas. The tree is particularly well known throughout New England. Normally, this species will attain a height of up to about 80 feet (24 meters), but as Table 1 indicates there are exceptions. The tree usually is found at altitudes below about 1400 feet (420 meters). The tree has large heart-shaped leaves, 6 to 8 inches (15 to 20 centimeters) in length. The wood is of straight-grain, lightbrown in color, and easily worked. The wood is used for some items of furniture, containers, and as a special millwood. When green, American basswood has a high moisture content and weighs 42 pounds per cubic foot (672.8 kilograms per cubic meter). After air-drying to 12% moisture, the weight is 26 pounds per cubic foot (416.5 kilograms per cubic meter) and 1000 board-feet (2.36 cubic meters) of nominal sizes weighs about 2170 pounds (984 kilograms). Crushing strength of the green wood when compression is applied perpendicular to the grain is 2220 pounds per square inch (15.2 MPa); of the dried wood, 4730 psi (32.6 MPa). The tensile strength with tension applied perpendicular to the grain is 280 psi (1.9 MPa) for green wood, 350 psi (2.4 MPa) for dried wood.

The white basswood is a smaller tree, ranging from 40 to 60 feet (12 to 18 meters) in height and essentially is found in the south. With preference for limestone soil, the tree ranges from southern New York through the mountains of Pennsylvania, following the Alleghenies southward into Georgia, Alabama, and central Florida. The tree also ranges westward into Kentucky and southern Indiana and Illinois. The wood is very much like that of *T. americana*. Other more regional species of American basswood include the *T. floridana* and the *T. caroliana*. A smaller tree, usually considerably less than 60 feet (18 meters) in height is the *T. michauxii* which has smaller leaves. It is found mainly in the southeastern United States, ranging westward into Texas. Among the more well known Tiliaceae in Europe are the lindens of Berlin. The *T. platyphyllos* is found throughout central and southern Europe and in the British Isles. These trees can attain a height up to about 135–140 feet (40.5 to 42 meters). The leaves range up to 5 or 6 inches (12.7 to 15.2 centimeters) across and are dark green. The fruit is pear-shaped. The common lime or European linden is a cross between the *T. platyphyllos* and *T. cordata*. The limes and lindens tend to be plagued with certain drawbacks, including a proliferation of suckers which occur around the base of the tree, their natural attraction to aphids which results in a production of honeydew that covers and blackens the leaves. The wood of the lime has attractive qualities for sculpting, the softness and workability permitting very intricate carving. Examples of carvings, as by Gibbons in the 1600s, still remain.

TABLE 1. RECORD BASSWOOD TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
American basswood (1993) (*Tilia americana*)	292	742	78	23.8	100	30.5	Pennsylvania
Carolina basswood (1996) (*Tilia caroliniana*)	74	188	84	25.6	46	14	Florida
White basswood (1997) (*Tilia heterophylla*)	223	566	116	35.4	57	17.4	North Carolina

BAST FIBERS. In the phloem, pericycle, or cortex of many plants there occur long slender thick-walled cells with tapering ends. These cells, often occurring in groups of considerable size, are often called bast fibers. They give to the stem of the plant considerable strength. Many bast fibers are useful to man, especially in the manufacture of cloth and cordage. Linen is made from the pericyclic fibers of flax, whereas hemp and ramie are coarser pericyclic fibers used in making coarse sacking and cordage. The phloem fibers of jute are also used for making rope and burlap, as well as the strong webbing used in upholstering furniture. Plant anatomists call them phloem fibers, pericyclic fibers, or cortical fibers.

Characteristics of natural rope fibers are given in Tables 1 through 4. See also **Rope**.

TABLE 1. MAJOR HARD ROPEMAKING FIBERS

General Name	Other Common Names	Botanical Name	Principal Sources
Abaca	Manila, abaca	*Musa textilis*	Borneo, Costa Rica, Guatemala, Honduras, Indonesia, Panama, Philippines
Cantala	Java cantala, maguey	*Agave cantala*	Indonesia, Madagascar.
Henequen	Mexican, Cuban, Carrizal, and Victoria sisal	*Agave fourcroydes*	Campeche (Mexico), Mexico, Yucatan Cuba, Northern
Sisalana	Sisal	*Agave sisalana*	Brazil, East Africa, Haiti, Indonesia, Malagasy Republic, West Africa

TABLE 2. MAJOR SOFT ROPEMAKING FIBERS

General Name	Other Common Names	Botanical Name	Principal Sources
Coir	Coconut fiber	*Cocos nucifera*	India, Indonesia, Pakistan, Philippines
Hemp (true) normally taking its name from source locality	Hemp	*Cannabis sativa*	Chile, Hungary, Italy, Poland, United States, Russia, former Yugoslavia
Jute	Jute	*Corchorus*	India, Indonesia, Pakistan

TABLE 3. TENSILE STRENGTH AND SPECIFIC GRAVITY OF ROPE FIBERS

Plant, Family, Or Grade	Relative Tensile Strength	Specific Gravity
Pita floja, Aechma magdalenae	104	n.a.
Manila Grade I, *Musa textilis*	100	1.43
Palma ixtle, *Yucca carenosana*	78	n.a.
Tequilana, *A. tequilana*	72	n.a.
Sisal, *Agave sisalana*	71	1.43
Zapupe maguey, *A. zapupe*	71	n.a.
Philippine maguey, *A. cantala*	54	n.a.
Henequen, *A. fourcroydes*	54	1.43
Jaumave ixtle, *A. heterocantha (funkiana)*	46	n.a.
Mexican maguey, *A. lurida*	36	n.a.
Tula ixtle, *A. lophanthi*	30	n.a.
Sansevieria	23	n.a.

BASTNASITE. A wax-yellow reddish-brown, greasy mineral of the composition (Ce, La) (CO_3) F, usually found in contact zones or associated with zinc lodes. Sometimes spelled *bastnaesite*. See also **Rare-Earth Elements and Metals**.

BATAGUR *(Reptilia, Chelonia).* Large fresh-water tortoises of several genera found in India and the Malayan region.

TABLE 4. BREAKING STRENGTH AND WEIGHT OF HARD ROPE FIBERS

Fiber Type	Breaking Strength Strain Strand (grains)	Weight/Yard (grains)
Abaca (manila). *Musa textilis* (highest)	46.5	0.567
Abaca (manila). *Musa textilis* (average)	34.7	0.772
Abaca (manila). *Musa textilis* (lowest)	31.1	0.962
Sisal, *A. sisalana*	22.6	0.616
Zapupe Vincent. *A. lespinassei*	21.6	0.722
Cabuya. *Furcrea cabuya*	20.1	0.575
Phormium. *Phormium tenax*	18.9	0.660
Henequen. *Agave fourcroydes*	16.8	0.766
Cantala. *A. cantala*	9.5	0.430

Conversion factor: 1 grain = 0.0648 gram.

BATES, HENRY WALTER (1825–1882). Henry Bates was a British naturalist who described mimicry in insects. Bates had little formal education. The eldest son of a Unitarian hosiery manufacturer in Leicester, he was apprenticed at the age of 13 to another local manufacturer. In the evenings he attended classes at the Mechanics' Institute, where he developed a gift for languages and music, and began to read very widely. Soon he was attracted to entomology, which brought him into contact with Alfred Russel Wallace. The two became friends, collected insects together, and corresponded after Wallace left Leicester early in 1845. In 1848 they sailed for the River Amazon to collect natural history specimens which they intended to sell in England to finance the trip. It was a daring plan, only made possible by both men having little to lose. They traveled together for nearly two years. Wallace returned in 1852, but Bates stayed until 1859, often ill, discouraged and isolated, but also thrilled by the tropical rainforest. He resided in Para, and then Santarem and Ega, making excursions into the interior. He collected some 14,712 animal species, primarily insects, of which around 8,000 were new to science. The sale brought scant return: his net profit was only £800. See also **Wallace, Alfred Russel (1823–1913)**.

During these travels, Bates was deeply interested in evolutionary ideas, having read Robert Chambers' anonymous *Vestiges of the Natural History of Creation*, which appeared in 1844. He observed the geographical distribution of insects, and believed he could see their diversification into different species, a subject he discussed with Wallace. Bates was an enthusiastic convert to the idea of natural selection on his return to Britain and used it to explain insect mimicry in his paper, "Contributions to an Insect Fauna of the Amazon Valley, *Lepidoptera: Heliconidae*," read at the Linnean Society of London on 21 November 1861. In this, Bates showed why one species of insect can come to resemble another: if a palatable insect mimics an unpalatable species it benefits from the protection afforded by the original. The closer the resemblance the better the protection. Bates proposed that this came about by natural selection, for example by birds eating the most imperfect copies so leaving the better copies to reproduce their kind. Charles Darwin was delighted by this striking example of natural selection in action. A little while later, Wallace also published on the issue. Batesian mimicry (where one species imitates another for disguise) should be distinguished from Müllerian mimicry, named after the naturalist Fritz Müller (1822–;1897), where a number of species converge and come to resemble each other.

Much encouraged by Darwin, Bates went on to write *The Naturalist on the River Amazon*, which was published in 1863. This has long been considered one of the best travel books of the era. Yet Bates found it difficult to get employment. In 1864 he was appointed assistant secretary of the Royal Geographical Society in London where he stayed until his death. He edited the Society's publications and carried on an immense correspondence with travelers all over the world while consolidating his reputation as a preeminent systematic entomologist. He was elected Fellow of the Linnean Society in 1871 and Fellow of the Royal Society in 1881.

JANET BROWNE, Wellcome Institute for the History of Medicine, London, UK

BATESON, WILLIAM (1861–1926). William Bateson was a British biologist and champion of Mendel's ideas in the English-speaking world, who postulated a nongenic "residue" involved in speciation.

Bateson was born in 1861; two years after the publication of Charles Darwin's *On the Origin of Species by Means of Natural Selection*, and four years after his classicist father became Master of St John's College, Cambridge (a post he held until his death in 1881). A governess helped foster William's early interest in natural history. He won a scholarship to Rugby school in 1875 where there began "a time of scarcely relieved weariness, mental starvation and despair." As an undergraduate at Cambridge (1879–1882) he did well in the natural sciences, but not in mathematics. At first he accepted the Darwinian natural selection paradigm with its emphasis on comparative anatomy as a way of deducing evolutionary relationships. With the encouragement of his friend W. F. Raphael Weldon, he spent the summers of 1883 and 1884 working with a leading American evolutionist, W. K. Brooks, on the marine worm *Balanoglossus*. A later student with Brooks was Thomas Hunt Morgan. Bateson's first publication was well received. His own assessment was given in a letter: "Five years hence no one will think anything of that kind of work, which will be very properly despised. It hasn't any bearing whatever on the things we want to know. It came to me at a lucky moment and was sold at the top of the market; presently steam will be introduced into Biology and wooden ships of this class won't sell well." See also **Morgan, Thomas Hunt (1866–1945)**; and **Weldon, Frank Raphael (1860–1906)**.

He was elected to a Fellowship at St John's College in 1885, and various other college appointments followed. In 1886, with a Royal Society grant and his passage smoothed by letters from two major figures in the Victorian science establishment, Thomas Huxley and Michael Foster, Bateson began field studies in Russia. The work disappointed Bateson scientifically, but his *Letters from the Steppe*, published posthumously, reveal a man of considerable culture, with a fine grasp of languages and of the foibles of humankind.

In 1888 Bateson set out to describe systematically the range of anatomical variations discernible in a wide variety of species, and coined the term *homoeotic* for a certain type of developmental mutant. On receiving a copy of his book *Materials for the Study of Variation Treated with Special Regard for Discontinuities in the Origin of Species* (1894), Huxley expressed appreciation: "that we are getting back from the region of speculation into that of fact again. There have been threatenings of late that the field of battle of Evolution has been transferred to Nephelococcygia [meaning nonsense]." See also **Huxley, Thomas Henry (1887–1975)**.

This reflected Huxley's campaign to undermine an attack on Darwin's natural selection as the major moving force in the origin of species, which had been launched in 1886 by Darwin's ex-research associate "The Philosopher" George Romanes. However, had Huxley read the book more thoroughly, he would have found that Bateson now took the same position. Bateson concluded that the data he had presented were "enough to show that the way taken has been wrong," and that: "the discontinuity of species ... has its origin not in the environment, nor in any phenomenon of adaptation, but in the intrinsic nature of organisms themselves, manifest in the original discontinuity of variation." See also **Romanes, George John (1848–1894)**.

What should have remained healthy scientific controversy grew bitter, and Bateson became engaged in public conflict with the biometricians including his old friend Weldon, who had become Professor of Zoology at University College London (1890), and was later the Linacre Professor of Comparative Anatomy at Oxford. Although elected a Fellow of the Royal Society in 1894, Bateson's first senior academic appointment was not until 1899 (Deputy to Professor Newton in the Zoology Department at Cambridge).

By 1900 Bateson had immersed himself for two decades in the evolutionary literature of his time and was involved with Edith Saunders in the type of breeding experiments Mendel had been carrying out in the 1860s. In 1900 came both the discovery of Mendel's paper, and an abstract by Michael Guyer in *Science*, describing the chromosomes in sterile hybrids. An attempt by Weldon to belittle Mendel was firmly dealt with in Bateson's book *A Defence of Mendel's Principles of Heredity* (1902). See also **Mendel, Gregor Johann (1822–1884)**.

However, the biometricians and orthodox Darwinians were still capable of influencing editorial, research funding, and appointment decisions. A later colleague, Reginald Punnett, noted that: "It was a difficult time for struggling geneticists when the leading journals refused to publish their contributions to knowledge and we had to get along as best we could with the more friendly aid of the Cambridge Philosophical Society and the *Reports of the Evolution Committee of the Royal Society*." See also **Punnett, Reginald Crundall (1875–1967)**.

Here, Bateson and Saunders published a major theoretical synthesis (1902) setting down basic concepts and terminology, much of which has stood the test of time. The books and papers that followed in the decades until his death in 1926 largely reiterated and amplified the points made in that paper. In 1906 Bateson suggested that "genetics," a word used at least as early as 1864 by Huxley, be the name of the emerging science. In 1908 an anonymous benefactor funded a Chair in Biology at Cambridge, to which Bateson was appointed for a five-year period. However, he resigned in 1910 to become Director of the John Innes Horticultural Institute at Merton in Surrey. See also **Genetics and Gene Science (Classical)**.

Some of the most significant aspects of the 1902 report were appreciated neither by Bateson's contemporaries, nor by those who came after. Most people recognized one form of hereditary information, corresponding to Mendel's "unit characters" (later called *genic information*), and it was not difficult to locate this to the chromosomes. Bateson postulated a "base" or "residue"'(later called *chromosomal information*) which, while associated with the unit characters, played an independent role in speciation: "The conception of Species, however we may formulate it, can hardly be supposed to attach to allelomorphic or analytical varieties [characters associated with conventional genes]. We may be driven to conceive "Species" as a phenomenon belonging to that "residue"."

Bateson's studies on large, slowly reproducing plants and animals were laborious and expensive. Meanwhile, T. H. Morgan and colleagues at Columbia University had begun studies on a small, rapidly reproducing organism, the fruit fly. Their results showed not only that genes were present on chromosomes, but also their linkage in linear order, their mutability, and their separability by recombination. Although Bateson and Punnett had demonstrated linkage (*gametic coupling*) in 1905, they had not at first interpreted it in chromosomal terms.

Because genes and chromosomes explained so much, the temptation to assume that they explained everything was overwhelming. Bateson did not succumb. Thus, while Bateson was cautious, in the second decade of the century Morgan and his school were "scrambling up the further bank." The "genic" paradigm, with a mathematical underpinning by the population geneticists, became in the 1930s "the modern synthesis," a dominating influence in the biosciences in the twentieth century.

Misunderstanding of Bateson continued long after his death. Without appreciating his concern about "the residue," twentieth-century commentators portrayed Bateson as irrationally failing to concede the chromosomal location of genes. Yet, repeatedly in his writings, while maintaining reservations Bateson, citing the work of Guyer and others, acknowledged this as the most plausible location. In 1973 the biologist A. G. Cock concluded that "Bateson's strength indubitably did not lie in theoretical innovation." In 1980 Harvard systematist Ernst Mayr classified Bateson as among those geneticists who failed to understand evolution, and the plant biologist G. Ledyard Stebbins blamed him for "delaying the synthesis." In 1983; Oxford zoologist Richard Dawkins lamented that "the irony with which we must now read W. Bateson's dismissal of Darwin is almost painful." In 1996 geneticist H. Allen Orr held that "Bateson was irredeemably confused about evolution." However, Bateson's ideas are now gaining support from studies of a phenomenon known as "Haldane's rule" by Horatio Naveira and Xulio Maside, and from the bioinformatic analyses of genomes by the present author. See also **Evolution (History)**; and **Mayr, Ernst Walter (1904–2005)**.

DONALD R. FORSDYKE, Queen's University, Kingston, Ontario, Canada

BATHOCHROME. A chromophore that lowers the frequency at which absorption occurs.

BATHOLITH. Batholith, by some writers spelled bathylith, is derived from the Greek meaning deep, and stone. It is a very large intrusive igneous mass with steeply inclined contacts, enlarging downward to undetermined depths. Typical batholithic rocks have a relatively coarse and even texture, such as granites and diorites. Batholiths occur as the roots or cores of folded and faulted mountain ranges and are therefore closely associated with mountain building, although probably not the cause of the deformation but rather consequent to it. The mode of emplacement of such large cross-cutting and relatively uniform igneous rock bodies has not yet been definitely determined. The term was proposed by Zuess in 1888.

BATHYMETRIC CHART. A map delineating the form of the bottom of a body of water, usually by means of depth contours (isobaths).

BATHYPELAGIC ZONE. A zone of the ocean into which small amounts of sunlight penetrate but in insufficient quantity to be of use to either plants or animals. See **Ocean Resources (Living)**.

BATHYTHERMOGRAPH (BT). A device for obtaining, from a ship under way, a record of temperature against depth (strictly speaking, pressure) in the upper 300 meters (984 feet) of the ocean.

For a thermal element it has a xylene-filled copper coil, which actuates a stylus through a Bourdon tube. The pressure element is a copper aneroid capsule that moves a smoked glass slide at right angles to the motion of the stylus. A double analog record is thus obtained as the BT is lowered and recovered. This device has generally been replaced by the expendable bathythermograph (XBT).

BATS *(Mammalia, Chiroptera).* Bats are most unusual animals and display features that required years of adaptation. Various kinds of bats are found nearly worldwide, with the exception of the polar regions and some barren desert areas. The fruit bats are found only in the tropics and subtropics of the Old World. Some families of insectivorous bats are restricted to specific areas of the world, while other families are found worldwide. The wide variety of forms is evident by the large number of species among the mammals. Bats are second only to rodents in number of species, and the consensus of scientists interested in bats is that a number of new species are waiting to be discovered and described.

Human interest in bats tends to focus on their uncanny ability to fly. In fact, it is the only mammal that *does* fly in terms of the definition of true flight.[1]

Designed for Flight. The front limbs of the bat have developed into *real* wings. In their early adaptation, this development became possible when the upper and lower arms, particularly the metacarpal bones and fingers, with the exception of the thumbs, grew unusually long. These bones serve as a support for the elastic wing membrane (*patagium*), which originates on both sides of the body. See Fig. 1. As can be noted from Fig. 2, from a distance the wings look something like portions of two umbrellas. The wing membrane is a continuation of the epidermis (skin), the pigment layer, and the corium (lower layer of skin containing blood vessels) of both sides of the body. The wing membrane of some species begins high on the back. It is very elastic and interlaced with fine muscle fibers and nerves. The blood vessels show independent rhythmical pulsations, which guarantee an equal supply of blood, even to the farthest regions of the membrane. The special stress on the front limbs during flight is met by the strongly developed flight muscles and the very firm humeral (shoulder) ligament. The large pectoral (chest) muscle is attached to the ossified sternum (breastbone), which has a flat rib in the middle, as in birds. The shoulder joint is a complex ball-and-socket joint, which allows the wings to turn in rowing movements.

[1] So-called flying lemurs, flying marsupials, flying squirrels, and scaly-tailed squirrels have a *flightskin* and can spread it and thus travel some distances through air, but their "flight" is accomplished by way of gliding. Their flight always exhibits a net downward direction, along the lines of a jump flight. Bats truly fly and for some distances.

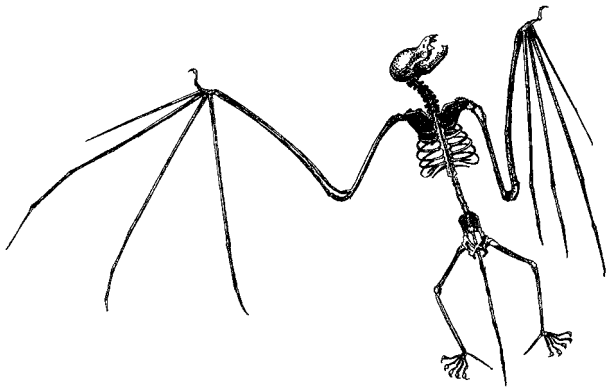

Fig. 1. Skeleton of Natterer's bat (*Tylonycteris nattereri*) clearly showing bone, joint, and cartilage structure. Note how arms and fingers of forelimbs have been extremely elongated, forming web-like structures that support filamentous skin-like fabric that can be continuously "flapped" for the flying mode and is so hinged that it will fold during resting, walking, and crawling positions, allowing the bat to perform essentially as a mammalian quadruped when on the ground and in trees and shrubs.

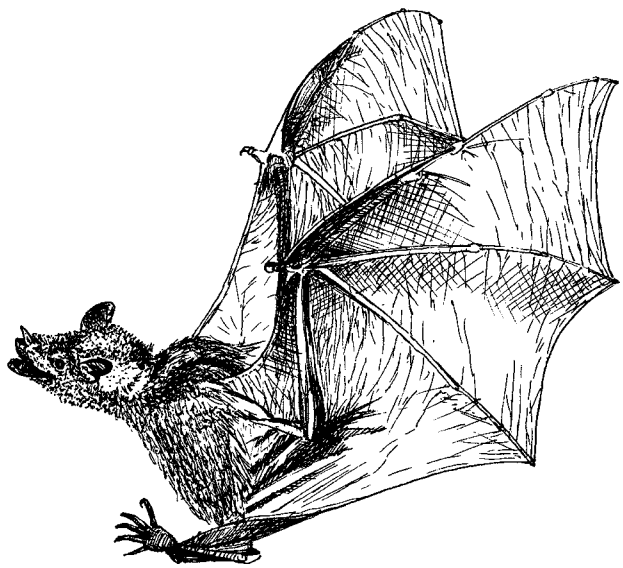

Fig. 2. Generalized sketch of the anatomy of the wing structure of a fruit-eating bat hovering over a flower. The wings are composed of flightskin which is supported by a complex bone and joint structure of the animal's forelimbs. Once a flight is over, the wing membranes are folded, enabling the bat to climb and run as a normal quadruped. (*Sketch suggested by high-speed photo made by M.D. Tubble.*)

The elbow, hand, and finger joints are hinged points that, together with the corresponding muscles, give a firm support to the outstretched wing surface. During rest, the wings are folded and lie close to the body, while the flightskin shrinks and becomes smaller.

Varying with species, the wingspan ranges from 3 to 40 centimeters (1.2 to 15.7 inches). Bats weigh from 4 to 900 grams (1.4 ounces to nearly 2 pounds). The front limbs have developed into wings, whereas the back limbs usually are relatively weak and serve mainly as body supports when walking and climbing. The knees, unlike those of other mammals (which are oriented to the front and bottom), are directed out and towards the back, because the pelvic joints are turned to the side. The feet have toes with strong claws, used for gripping and hanging. The center of gravity is in the middle of the body because of the powerfully developed chest and weak development of the back legs and pelvic girdle. The body is held in a stable position during flight. When resting, bats position their bodies so that the head is down. See Fig. 3. They have between 20 and 32 teeth. The intestine is short, especially in insectivorous bats, and thus genus *Lasiurus*. Bat give birth usually to one and rarely to two young. As will be noted from Table 1, there are two suborders of bats: (1) fruit bats (*Megachiroptera*) and (2) insectivorous

Fig. 3. During the day, fruit bats sleep, hanging upside down, wrapped up in their wing membranes. Sketched here is a *Pteropus capistratus*. When the temperature rises, the "cloak" is opened up and used to fan air.

bats (*Michrochiroptera*). There are 19 families, approximately 200 genera, and about 800 species.

In normal flight, bats do not move their wings from top to bottom and back again; instead they make a rotating motion so that the tips of the wings follow an elliptical course. See Fig. 4 on p. 387. The downstroke moves from *high in back* to *low in front* to *high in back*, with the narrow side of the wing facing forward. The concept that the flight of these mammals is clumsy fluttering as compared with the elegant flight of many birds is *incorrect*.

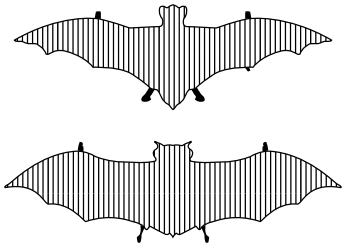

Fig. 4. The flight patterns of specific species of bats can be deduced from the shape of the wings. (Above) The long, narrow wings of the rapid-flying common nocturne bat (*Nyctalus noctula*. (Below) The wider wings of the much slower greater horseshoe bat (*Rhinolophusferrumequinum*).

The number of wing strokes depends mainly on the size of the animal. In large fruit bats, the rowing strokes are made much more slowly than in the smaller insectivorous species. The flight of the larger bats can be compared with that of crows and ravens. Some of the larger bats make about 10 to 12 wing strokes per second during a normal flight distance. In contrast, smaller bats make approximately 17 to 18 wing strokes per second. See Fig. 5 on p. 387. Some species, such as the blossom feeders, have a hovering flight during which the animal is able to suspend itself in midair for a long period of time, with its body erect.

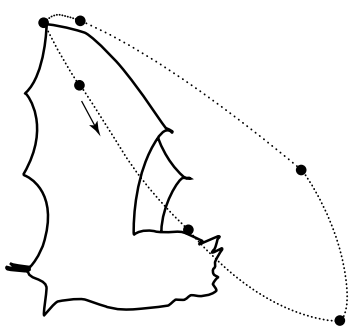

Fig. 5. The wing tips of an insectivorous bat follow an elliptical course during flight. During the upward stroke the flightskin is somewhat folded to reduce the air resistance. The bat shown is the lesser horseshoe bat (*Rhinolophus hip posideros*).

Many bats build up the necessary initial velocity to get airborne by dropping from their resting place, stretching their wings, and flying away in rowing flight. Other species raise their bodies from the perpendicular resting position to a horizontal flight position with a few wing strokes. Only then do they release their feet from their resting place. Most insectivorous bats are able to take off from the ground by making a small jump. The flight speed is reduced on landing by a turning of the wings and the tail flightskin. When insectivorous bats wish to land on a wall or branch, they maneuver their bodies into a downward orientation with one final wing stroke during the last phase of the approach, and then immediately hold on to the resting place with the talons of their hind toes.

Climbing and Running. Once the bat has folded its wing membrane, it becomes a real quadruped. When climbing or running, it draws itself up by the cushionlike, callous pads at its wrists and is supported by the soles of the hind feet. The feet are turned out, somewhat apart from the body, in straddle fashion. Bats *do not* move around awkwardly on the ground, as is so often presumed. Some species are rather good runners. They also can climb excellently, with the thumb and claw playing important roles.

Other Classifications. In addition to taxonomic classes, bats also may be grouped in accordance with their general behavior. (1) There are the community-minded and commuting bats which live in isolated habitats a short distance from their feeding grounds, remaining in large trees or caves by day and seeking their food supply at night. Some types of bats prefer to fly out at evening en masse and return at predawn to their home base. Other bats leave their haunts on essentially an individualistic basis and return individually as their hunger has been satisfied. (2) There are the highly individualistic or isolationist types of bats that elect essentially to live and forage alone. It has been estimated that a group of insect-eating bats that once lived in Ney Cavern (Texas) numbered as high as 20 million. Any cave with reasonable entry can almost be counted on as a bat roost. Thousands upon thousands of bats also live together in groups of trees. Evening flights of bats have been likened to a large cloud of smoke, causing a darkening of the sky for some distance. Records also indicate that large boughs of trees have been snapped because of the weight of the bats roosting on them. Hollows in trees are also favorite haunts for bats. Since the early 1950s, there appears to be a reduction of massive bat populations occurring and several theories have been advanced. It could well be that this is a manifestation of some natural cycle not yet fully understood. A decreasing bat population, of course, is cause of some concern because they play an effective natural role in controlling insects. Some records indicate correspondence between local bat populations and the incidence of malaria in selected tropical areas. But probably much more important is the economic value of the bats in terms of killing off hordes of insects that damage agricultural crops. In contrast, however, the fruit-eating bats can be an economic menace to orchards. Certain conventional protective means, such as smoke generation or floodlighting, have proved quite ineffective against the bats.

Bat Sonar. Ages before scientists developed sonar and radar, bats had been using sound waves for communication and navigation. At one time, it was felt that this faculty was unique to bats, but later investigations showed that a number of animals also use such means, including some of the fishes (a form of underwater sonar). It can be stated with some confidence, however, that the insect-eating bats probably have developed the technique to the greatest perfection.

For decades, experimenters knew that if the eyes of a bat were blindfolded, this action seemed to have little effect on the animal's maneuverability. But many years later and within the past few decades, when experimenters taped one or both ears shut, it was obvious that the animal no longer could navigate. Experiments have been conducted in which hundreds of wires have been crisscrossed over an enclosure to demonstrate the sonic guidance of the bats. It is now known, of course, that bats emit supersonic radiation ranging up to 30,000 Hz, but that radiation as low as 200 Hz also can be emitted. This sound can be maintained for long periods throughout the flight of the animal. The sounds are emitted through the animal's nostrils and are aided by a complex flap structure to provide precise directivity to the radiation. Echo returns from such emissions enable a bat to pick out a tiny flying insect some distance ahead. Of course, this highly refined navigation system would be ineffective if the bat could not acrobatically maneuver while in flight. This they can do in adjusting their course where signals only a few inches (centimeters) ahead are received by their highly complex and sensitive ears. These attributes,

TABLE 1. TWO SUBORDERS OF BATS

Order Bats (Chiroptera)
Suborder Fruit Bats (Megachiroptera)

Family Fruit Bats (Pteropidae)

Subfamily Flying Foxes (Pteropina)
- Genus *Dobsonia*
- Genus *Eidolon*
  - Straw-colored bat, *E. helvum*
- Genus Rousette Bats (*Rousettus*)
  - Egyptian Fruit Bat, *R. aegyptiacus*
  - *R. a. aegyptiacus*
  - *R. a. leachi*
  - *R. a. occidentalis*
  - Angolan Fruit Bat, *R. angolensis*
  - *R. a. angolensis*
  - *R. a. smithi*
  - *R. a. ruwenzorii*
- Genus *Myonycteris*
  - Collared Fruit Bat, *M. torquata*
- Genus Flying Foxes (*Pteropus*)
  - Tonga Flying Fox, *P. tonganus*
  - *P. niger robinsoni*
  - *P. alecto gouldi*
  - Indian Flying Fox, *P. giganteus*
  - *P. g. giganteus*
  - *P. g. leucocephalus*
  - Red-necked Fruit Bat, *P. vampyrus*
  - *P. v. vampyrus*
  - Gray-headed Flying Fox, *P. poliocephalus*
  - P. subniger
  - Rufous Flying Fox, *P. rufus*
  - *P. capistratus*

Subfamily Epauletted Fruit Bats (Epomophorinae)
- Genus *Epomops*
  - Franquet's Epauletted Fruit Bat, *E. franqueti*
  - Büttikofer's Epauletted Fruit Bat, *E. Büttikoferi*
- Genus *Epomophorus*
  - Wahlberg's Epauletted Fruit Bat, *E. wahlbergi*
  - *E.w. wahlbergi*
  - *E.w. haldemani*
- Genus *Micropteropus*
  - Dwarf Epauletted Fruit Bat, *M. pusillus*
- Genus *Hypsignathus*
  - Hammer-headed Fruit Bat, *H. monstrosus*
- Genus *Scotonycteris*
  - Zenker's Fruit Bat, *S. zenkeri*
  - Snake-toothed Bat, *S. ophiodon*

Subfamily Short-nosed Fruit Bats (Cynopterinae)
- Genus *Cynopterus*
  - Indian Short-nosed Fruit Bat, *C. sphinx*

Subfamily Tube-nosed Fruit Bats (Nyctimeninae)
- Genus *Nyctimene*
  - Large Tube-nosed Fruit Bat, *N. major cephalots*
  - Queensland Tube-nosed Fruit Bat, *N. Robinsoni*
- Genus Lesser Tube-nosed Fruit Bats (*Paranyctimene*)

Family Long-tongued Bats (Macroglossidae)
- Genus *Eonycteris*
  - Dobson's Long-tongued Dawn Bat, *E. spelaea*
- Genus *Macroglossus*
  - *M. lagochilus*
  - Dwarf Long-tongued Fruit Bat, *M. minimus*
- Genus *Megaloglossus*
  - African Long-tongued Fruit Bat, *M. woermanni*
- Genus *Notopteris*
- Genus *Nesonycteris*

Family Harpy Fruit Bats (Harpyionycteridae)
- Genus *Harpyionycteris*
  - Whitehead's Harpy Fruit Bat, *H. whiteheadi*

Suborder Insectivorous Bats (Microchiroptera)

Superfamily Emballonuroidea

Family Rat-tailed Bats (Rhinopomatidae)
- Genus *Rhinopoma*
  - Larger Rat-tailed Bat, *R. microphyllum*
  - Lesser Rat-tailed Bat, *R. hardwickei*

Family Sac-winged Bats (Emballonuridae)

Subfamily Emballonurinae
- Genus Old World Sheath-tailed Bats (*Emballonura*)
- Genus Coleura
- Genus Sac-winged Bats (*Balantiopteryx*)
- Genus *Rhynchonycteris*
  - Proboscis Bat, *R. naso*
- Genus Sheath-tailed Bats (*Saccopteryx*)
  - Two-lined Sheath-tailed Bat, *S. bilineata*
- Genus Tomb Bats (*Taphozous*)
- Subgenus *Taphozous*
  - Tomb Bat, *T. (Taphozous) perforatus*
  - Mauritian Tomb Bat, *T. (Taphozous) mauritianus*
- Subgenus *Liponycteris*
  - Naked-bellied Tomb Bat, *T. (Liponycteris) nudiventris*
- Subgenus Pouch-bearing Bats (*Saccolaimus*)

Subfamily Diclidurinae
- Genus *Diclidurus*
  - Ghost Bat, *D. albus*

Family Bulldog Bats (Noctilionidae)
- Genus *Noctilio*
  - Mexican Bulldog Bat, *N. leporinus*
  - Dent's Horseshoe Bat, *R. denti*
  - Lander's Horseshoe Bat, *R. landeri*
  - *R. alcyone*
  - Greater Horseshoe Bat, *R. ferrumequinum*
  - Hildebrandt's Horseshoe Bat, *R. hildebrandtii*
  - Mediterranean Horseshoe Bat, *R. euryale*
  - Blasius Horseshoe Bat, *R. blasii*
  - Mehely's Horseshoe Bat, *R. mehelyi*

Family Old World Leaf-nosed Bats (Hipposideridae)
- Genus *Hipposideros*
  - Commerson's Leaf-nosed Bat, *H. commersoni*
  - Angolan Leaf-nosed Bat, *H. c. gigas*
  - South African Lesser Leaf-nosed Bat, *H. caffer*
  - Greater Himalayan Leaf-nosed Bat, *H. armiger*
  - *H. jonesi*
- Genus *Asellia*
  - Trident Leaf-nosed Bat, *A. tridens*
- Genus *Anthops*
  - Flower-faced Bat, *A. ornatus*
- Genus *Triaenops*
  - Persian Leaf-nosed Bat, *T. persicus*

Superfamily Phyllostomoidea

Family Leaf-nosed Bats (Phyllostomidae)

Subfamily Mustache Bats (Chilonycterinae)
- Genus *Chilonycteris*
  - Mustache Bat, *C. personata*
- Genus *Pteronotus*
  - Suapure Naked-backed Bat, *P. suapurensis*
  - Naked-backed Bat, *P. davyi*

TABLE 1. (*Continued*)

Suborder Insectivorous Bats (Microchiroptera)

Subfamily Big-eared Leaf-nosed Bats (Phyllostominae)
- Genus *Lonchorrhina*
  - Tome's Long-eared Bat, *L. aurita*
- Genus *Macrophyllum*
  - Long-legged Bat, *M. macrophyllum*
- Genus Spear-nosed Bats (*Phyllostomus*)
  - Spear-nosed Bat, *P. hastatus*

Subfamily Long-tongued Bats (Glossophaginae)
- Genus *Glossophaga*
  - Long-tongued Bat, *G. soricina*
  - Southern Bulldog Bat, *N. labialis*

Superfamily Megadermatoidea

Family Slit-faced Bats (Nycteridae)
- Genus *Nycteris*
  - Great Slit-faced Bat, *N. grandis*
  - Geoffroy's Slit-faced Bat, *N. thebaica*
  - Hispid Slit-faced Bat, *N. hispida*
  - Javanese Slit-faced Bat, *N. javanica*

Family Large-winged Bats (Megadermatidae)
- Genus *Lavia*
  - African Yellow-winged Bat, *L. frons*.
- Genus False Vampires (*Megaderma*)
- Subgenus *Cardioderma*
  - Heart-nosed False Vampire, *M. (Cardioderma)*
- Subgenus *Lyroderma*
  - Indian False Vampire, *M. (Lyroderma) lyra*
- Subgenus *Megaderma*
  - Malayan False Vampire, *M. (Megaderma) spasma*
- Genus *Macroderma*
  - Australian Giant False Vampire Bat, *M. gigas*

Superfamily Horseshoe Bat Relatives (Rhinolophoidea)

Family Horseshoe Bats (Rhinolophidae)
- Genus *Rhinolophus*
  - Maclaud's Horseshoe Bat, *R. maclaudi*
  - Lesser Horseshoe Bat, *R. hipposideros*
- Genus *Artibeus*
  - Dwarf Fruit-eating Bat, *A. nanus*
  - Big Fruit-eating Bat, *A. lituratus*
  - Jamaican Fruit-eating Bat, *A. jamaicensis*
- Genus *Uroderma*
  - Tent-building Bat, *U. bilobatum*
- Genus *Centurio*
  - Wrinkle-faced Bat, *C. senex*

Family Vampire Bats (Desmodontidae)
- Genus *Desmodus*
  - Vampire Bat, *D. rotundus*
- Genus *Diaemus*
  - White-winged Vampire Bat, *D. youngi*
- Genus *Diphylla*
  - Hairy-legged Vampire Bat, *D. ecaudata*

Superfamily Vespertilionid Bats (Vespertilionoidea)

Family Funnel-eared Bats (Natalidae)
- Genus *Natalus*
  - Funnel-eared Bat, *N. stramineus*

Family Smokey Bats (Furipteridae)
- Genus *Furipterus*
  - Smokey Bat, *F. horreus*

Family Disk-winged Bats (Thyropteridae)
- Genus *Thyroptera*
  - Spix's Disk-winged Bat, *T. tricolor Spix*, 1823
  - Honduran Disk-winged Bat, *T. discifera*

Family Sucker-footed Bats (Myzopodidae)
- Genus *Myzopoda*
  - Golden Bat, *M. aurita*

Family Vespertilionid Bats (Vespertilionidae)
Subfamily Vespertilioninae
- Genus *Tylonycteris*
  - Flat-headed Bat, *T. pachypus*
- Genus Mouse-eared Bats (*Myotis*)
  - Large Mouse-eared Bat or European Little Brown Bat, *M. myotis*
  - Pale Spear-nosed Bat, *P. discolor*
- Genus *Trachops*
  - Fringe-lipped Bat, *T. cirrhosus*
- Genus *Vampyrum*
  - Linné's False Vampire Bat, *V. spectrum*

Subfamily Long-tongued Bats (Glossophaginae)
- Genus *Glossophaga*
  - Long-tongued Bat, *G. soricina*
- Genus *Platalina*
  - *P. genovensium*
- Genus *Choeronycteris*
  - Mexican Long-nosed Bat, *C. mexicana*
- Genus *Musonycteris*
  - Banana Bat, *M. harrisoni*

Subfamily Phyllonycterinae
- Genus *Phyllonycteris*

Subfamily Short-tailed Leaf-nosed Bats (Carolliinae)
- Genus *Carollia*
  - Seba's Short-tailed Bat, *C. perspicillata*

Subfamily Yellow-shouldered Bats (Sturnirinae)
- Genus *Sturnira*
  - Yellow-shouldered Bat, *S. lilium*

Subfamily Red Fruit-eating Bats (Stenoderminae)
- Genus *Ectophylla*
  - White Bat, *E. alba*
- Genus *Barbastella*
  - Barbastelle, *B. barbastellus*
- Genus *Plecotus*
  - Long-eared Bat, *P. auritus*

Subfamily Miniopterinae
- Genus *Miniopterus*
  - Long-winged Bat, *M. schreibersi*

Subfamily Murininae
- Genus Tube-nosed Bats (*Murina*)
- Genus Hairy-winged Bats (*Harpiocephalus*)

Subfamily Nyctophilinae
- Genus *Antrozous*
  - Pallid Bat, *A. pallidus*

Family New Zealand Short-tailed Bats (Mystacinidae)
- Genus *Mystacina*
  - New Zealand Short-tailed Bat, *M. tuberculata*
  - Mediterranean Bat, *M. oxygnathus*
  - Bechstein's Bat, *M. bechsteini*
  - Pond Bat, *M. dasycneme*
  - Water Bat, *M. daubentoni*
  - Long-fingered Bat, *M. capaccinii*
  - Geoffroy's Bat, *M. emarginatus*
  - Natterer's Bat, *M. nattereri*
  - Whiskered Bat, *M. mystacinus*
  - Welwitsch's Bat, *M. welwitschii*
- Genus *Pizonyx*
  - Fish-eating Bat, *P. vivesi*
- Genus Pipistrelles (*Pipistrellus*)
  - Common Pipistrelle, *P. pipistrellus*
  - Nathusius' Pipistrelle, *P. nathusii*
  - Kuhl's Pipistrelle, *P. kuhli*
  - Savi's Pipistrelle, *P. savii*
  - African Banana Bat, *P. nanus*
  - West African Pipistrelle, *P. nanulus*

of course, explain why a half million or more bats can fly around in a darkened cave without fear of frequent collisions.

Although bats depend principally upon sound as a means of navigation and collision avoidance, the old saying "blind as a bat" is not true. Most likely, a bat cannot sense color, nor are its eyes large or considered important to its well-being or locomotion; however, these animals do have all of the elements found in a normal mammal eye, and laboratory research has shown that the bat's ability to see does assist it in certain behavioral situations.

Insectivorous Bats. The *Megachiroptera* (meaning big bat) is the largest grouping, but is better identified as the *fruit-eating* bats. As shown in the classification table, the insectivorous bats are in three major classes. The Flying Foxes are the largest group and also have the greatest wingspan (5 feet (1.5 meters)). They are found in Australia, Indonesia, the eastern Pacific, in the Oriental Region in areas that perimeter the Indian Ocean, including much of India, and off the east coast of Africa on the Comoro Islands and Madagascar. They are not found on the African continent per se. They are of many colors, sizes, with large ears, and long tails.

There are many more varieties of insect-eating bats. The classification in detail is far from complete. In these bats, the tail can be extended or retracted. By variously manipulating the tail, the animal has an excellent steering mechanism. The Tomb-Bat (*Taphozous*) was named for the frequency with which it has been found in ancient Egyptian tombs. Vampire bats are of particular interest because they feed only on animal blood and this can range from humans on down the scale. They are quite gruesome in appearance, having naked noses, pointed ears, and spherical bodies. They move about on the ground like great spiders. They are also good fliers. There is a misconception that the vampire bat sucks blood from its victim. In actuality, the vampire bat runs on all fours to its intended victim, jumps on the victim's body and slashes the skin with its two chisel-shaped upper front teeth. The bat then laps up the blood exuding from the wound. The vampire bat also is believed to spread a calming scent before the attack. Millions of these bats live in the tropical area south from the United States to Argentina. Because these bats feed occasionally on human beings, more frequently on horses, and other domestic animals, they can carry diseases, such as rabies, Murrina, Chagas disease, and other serious infectious maladies. They are seriously regarded in Central and South America. They appear to be migrating slowly northward and may one day be a threat to cattle raising in the southwest of the United States.

The Little Brown Bats are small, about $3\frac{1}{2}$ inches (9 centimeters) in length, and are found throughout the United States and temperate climates. They feed on insects during the warm season and usually hibernate in caves during the winter months. Some of the specialized bats include the Big-eared Bats, well named; the Mastiff Bats, which have peculiarly shaped ears, giving the face a mastiff-like appearance; the Horseshoe-nosed Bats, which have leaf-like appurtenances; and the Mexican Free-tailed Bats, which hang in colonies of hundreds of thousands in a given locale.

The Hare-lipped Bats are fish eaters and are found in tropical Central and South America. They grasp small fish with their elongated toes and claws. The Long-nosed Bats feed on nectar and pollen. Particularly in connection with night-blooming flowers, these bats play an important cross-fertilizing role.

Vampire Bats and Their Social Habits. Until recent years, natural scientists have tended to concentrate on researching an animal's physiology prior to concentrating their efforts on the animal's social organization. In a special study of vampire bats, however, it has been found that they have a reasonably developed social life, particularly among their female members.

Vampire bats are common in tropical America and often will be found living in land that has been converted to use as pasture for cattle. Horses also are common prey and, in fact, usually preferred. The vampire bats attack their prey every night, often depending upon the phase of the moon because they prefer near-darkness, so as not to alert their prey, which are identified by a combination of odor and sound (echo location). Once attached to the target prey (usually commencing at the tail or mane, heat-sensitive nasal cells detect where the blood is flowing near the surface of the prey's body. The vampire bats have razor-sharp incisors and, because of anticoagulant in the bat's saliva, blood from a wound continues to flow for up to a half-hour. This is the usual duration of a meal of blood for a given bat per night.

To sustain a healthy life, the vampire bat must consume from 20 to 30 milliliters of blood every 60 hours.

In an extended study by McNab (University of Florida) *http://www.zoo.ufl.edu/Faculty/fac99.html*, it was found that a bat that is unsuccessful in feeding over two consecutive nights has little chance for survival unless helped. From 50 to 100% of a bat's body weight must be consumed each night to sustain a healthy condition. In such instances, McNab found that some female bats will help other females by regurgitating blood to some of the less fortunate members of the colony. Thus, vampire bats pose an interesting scientific base for studying sharing and altruism among animals.

Humans, of course, are well known for sharing their food supplies, particularly during emergency situations. Other animals found to share food supplies include wild dogs, chimpanzees, and hyenas, although much more research is required to determine the details of such social behavior.

BATTEN DISEASE. An inherited disorder that leads to a progressive deterioration of the brain and nervous system, and inevitably leads to an early death. Because vision loss is one of the earliest signs of the disease, it is often first suspected during an eye exam.

Although the term Batten disease has historically been used to describe the juvenile form of a disorder called *neuronal ceroid lipofuscinosis* (NCL), it is now commonly used to describe all forms of NCL, including those that occur after childhood. The disease was named after the British pediatrician who first described it in 1903. It is not contagious and, at present, there is no cure or treatment.

Classified by age, there are four different forms of Batten disease, each genetically different:

- Infantile, which begins between the ages of 6 months and 2 years.
- Late infantile, which begins between the ages of 2 and 4.
- Juvenile, which starts between 5 and 9 years.
- Adult, which generally occurs before the age of 40.

The infantile forms of the disease progress most rapidly, usually resulting in death by midchildhood, while those with the juvenile form may live into their twenties. Adult NCL causes milder symptoms, but life expectancy is shortened.

The development of Batten disease is connected to a buildup of lipopigments in body tissues, including cells of the brain, the eye, the skin, and muscles. Although scientists are uncertain about why this buildup occurs, it is suspected that there is a shortage of enzymes that would normally break down the lipopigments or a glitch in the cells causing them to produce too much of the substances. Scientists have been unable to determine why the excess lipopigments cause damage to the nerve cells.

All types of Batten disease are inherited, although different forms of the disease are caused by different gene combinations. The childhood forms occur when each parent carries a recessive gene, meaning that each pregnancy has a 1 in 4 chance of containing the gene combination necessary for developing the disease. Those who carry just one defective gene are known as carriers, meaning they do not develop the disease but they can pass it along to their children. Adult forms of Batten disease may be either recessive, as in the childhood forms, or (rarely) autosomal dominant, meaning that any person who inherits the single gene will develop the disease.

Batten disease is often first suspected by an ophthalmologist because, except in the adult form, vision loss is one of the earliest symptoms. The childhood forms of Batten disease all involve the loss of cells within the eye, which can be detected by an eye doctor. Because this cell loss can also occur with other diseases, however, the child is usually referred to a neurologist for final diagnosis. Further testing may include blood and urine tests, skin or tissue sampling, an electroencephalogram (EEG), electrical studies of the eyes, and brain scans. The imaging technique most commonly used is computed tomography (CT), which uses a computer and x-rays to create a picture of the brain's structure. This scan can determine whether there may be decaying areas of the brain.

The first symptoms in the childhood forms usually occur between the ages of 5 and 10 and, in addition to vision loss, may include seizures, subtle personality and behavior changes, clumsiness, and slow learning ability.

There is no specific treatment for Batten disease at this time, although some symptoms can be controlled. Seizures, for instance, can sometimes be reduced with anticonvulsant drugs. There is some evidence that treatment with vitamins C and E, along with diets low in vitamin A, may slow the development of the disease in children. These treatments do not, however, prevent the fatal outcome of the disease.

Physical and occupational therapy are also used to help patients retain function as long as possible. Because the disease produces extreme disability and dementia, patients and families often find support groups helpful in providing assistance and encouragement.

Vision Rx, Inc., Elmsford, NY

BATTERY. One or more galvanic cells in a finished package constitute a battery. The cells may be electrically connected in various series, parallel, and series-parallel combinations, including discrete groupings with separate terminals. In each individual cell of the battery, two electrodes of dissimilar materials are normally joined by an ion-carrying path, but are separated by an electron insulator. The electron transfer carrying path is external, via some conductor, such as a metal wire, through a using device where the work is done. The ion path is internal via an electrolyte that is an ionizable salt dissolved in a solvent. The electrolyte may be solid or liquid, although the former is usually limited to low discharge rates.

The active material of the solid electrodes may be solid, gaseous, or liquid and, in some special cases, such as with certain types of liquid cathode cells, the cathode serves a dual role as electrolyte solvent and de-polarizer.

Control of the discharge is usually by a switch in the electron-carrying circuit, but in some special cases, it is done by making or breaking the ion-carrying path.

The cells may be rechargeable and such are often called "secondary" or "storage" batteries. Secondary batteries are reversed by passing a current through the cells in the opposite direction of current flow discharge. The chemical conditions of the undischarged battery are restored and the cells are ready to be discharged again. Primary cells are meant to be discharged to exhaustion only once and then discarded. Some of the electrochemical systems used in "primary" cells are reversible, but the cells do not have the physical features needed to render them *safely* rechargeable. Various schemes or devices have been proposed over the years to recharge "primary" batteries, but generally, they are impractical and sometimes potentially *dangerous*.

Both primary and secondary types are produced in "wet-" and "dry"-cell versions. Wet cells are liquid electrolyte cells sensitive to orientation, whereas dry cells are not. Dry cells can also be made with liquid electrolytes, but in such cases, the electrolyte is immobilized by some mechanism, such as gelling or holding it in absorbent media, such as paper. Solid electrolyte cells are, by definition, dry cells.

As a further variation, both primary and secondary cells can be made as *reverse cells*. Activation is held off until just prior to use of the battery. This may involve holding off addition of liquid electrolyte or the solvent. One approach is internal storage of the liquid electrolyte or solvent apart from the active material is an ampoule. Activation is done by breaking the storage ampoule. Cells in which the electrolytes are inert solids at storage temperatures, are actuated by heating to above the melting point. An example of another type of reserve battery is that used for oceanographic studies. It is an air-depolarized magnesium anode battery that uses seawater as the electrolyte. The battery is activated when it is partly submerged in the ocean.

Both primary and secondary batteries are marketed in a wide variety of sizes and shapes, from the little "button" cells used in watches and hearing aids to the huge rectangular cells for missile batteries and load-leveling power storage units. Some applications also involve stringent conditions, such as very low ($-50\,^{\circ}C$) or very high (above $200\,^{\circ}C$) operating temperatures, underwater usage, outer-space usage, continuous or intermittent discharge, and discharge that may be spread out over several years, or a very short period, such as a few seconds. With the larger sizes, energy per unit weight is usually the important criterion, especially in rockets or electric vehicles. With the smaller sizes, output per unit volume is usually more meaningful.

There are also cells that convert light and heat into electricity. These are solar cells and thermal cells.

The number of electrochemical systems, the variations in cell sizes and internal configurations and the specialized applications for commercially available batteries all have increased dramatically during the past 40 years and change is continuing at a rapid pace. Good examples of the changes are the non-aqueous batteries now on the market. All of those offered so far are with lithium anodes, but they are available in a wide range of sizes and in solid cathode, liquid cathode, and solid electrolyte versions. The rapidly changing price of raw materials is a significant factor. For example, a rise in the price of silver resulted in a switch from aqueous, silver oxide/zinc cells to non-aqueous types for many applications, such as some types of wristwatches. The development and design of galvanic cells and batteries has therefore become an increasingly complex science, far removed from the near art it was in pre-World War II years. See Table 1.

Cell Electrochemical Systems and Designs

The simplest cell would consist of two dissimilar metals in an ionically conductive medium, provided that the combination yields a voltage above that needed to break down the electrolyte continuously. The electrode where the electrolyte is broken down upon the receipt of electrons is

TABLE 1. CHARACTERISTICS OF SOME COMMERCIALLY AVAILABLE BATTERIES

Battery System	Basic Type	Overall Chemical Reaction	Negative Electrode	Positive Electrode	Electrolyte	Nominal Voltage per Cell	Energy Density Watt-hours		Capacity	Input or Recharging	Advantages	Disadvantages
							Per Pound	Per Cubic Inch				
Zinc-manganese dioxide (usually called Leclanche or carbon-zinc)	Primary	$2MnO_2 + 2NH_4Cl + Zn \rightarrow ZnCl_2 \cdot 2NH_3 + H_2O + Mn_2O_3$	Zinc	Manganese dioxide (Often an ore)	Aqueous solution of ammonium chloride, zinc chloride	1.5	5–40	1–3	Several hundred mAh to 30 Ah*	—	Low cost; variety of shapes and sizes; excellent shelf life	Efficiency decrease at high current drains; poor low-temperature performance
Zinc-zinc chloride-manganese dioxide	Primary	$4Zn + 8MnO_2 + ZnCl_2 + 8H_2O + xH_2O \rightarrow 8MnOOH + ZnCl_2 \cdot 4Zn(OH)_2 \cdot xH_2O$	Zinc	Manganese dioxide (usually synthetic)	Aqueous solution of zinc chloride	1.5	15–30	1–3	Several hundred mAh to several Ah	—	Good service at high current drain, leak resistant, good low-temperature performance	Relatively expense for low drains
Zinc alkaline-manganese dioxide	Primary	$2Zn + 3MnO_2 \rightarrow 2ZnO + Mn_3O_4$	Zinc	Manganese dioxide (usually synthetic)	Aqueous solution of potassium hydroxide	1.5	20–40	2–3	Several hundred mAh to several Ah	—	High efficiency under moderate continuous drain conditions; good low-temperature performance; low impedance; long shelf life	Expensive for low drains
	Rechargeable	$Zn + 2MnO_2 \rightleftharpoons ZnO + Mn_2O_3$				1.5	10	1.0–1.2		Slightly over 100% of energy withdrawn		Rechargeable-limited cycle life; voltage limited taper current charging
Zinc-mercuric oxide	Primary	$Zn + HgO \rightarrow ZnO + Hg$	Zinc	Mercuric oxide	Aqueous solution of potassium hydroxide	1.35	10–50	4–8	16 mAh-14 Ah	—	High service capacity/volume ratio; flat voltage discharge characteristic; good high-temperature performance good storage life	Poor low-temperature performance on some types Expensive
Zinc-silver oxide	Primary	$Zn + Ag_2 \rightarrow ZnO + 2Ag$	Zinc	Monovalent silver oxide	Aqueous solution of potassium hydroxide or sodium hydroxide	1.5	30–60	4–8	38–190 mAh	—	Good high current pulsing; flat voltage discharge	Silver is expensive poor storageability

	Rechargeable	$Zn + AgO + H_2O \rightleftharpoons Zn(OH)_2 + Ag$		Silver oxide	Aqueous solution of potassium hydroxide	1.5	30–60	2–8	5 Ah to several thousand Ah	Over 100% of energy withdrawn	High-energy density; high rate capability	Expensive; poor charge maintenance limited cycle life
Silver-cadmium	Rechargeable	$Cd + AgO + H_2O + KOH \rightleftharpoons Cd(OH)_2 + Ag + KOH$	Cadmium	Divalent silver oxide	Aqueous solution of potassium hydroxide	1.4	22–34	1.8–2.5	Sealed, up to 300 Ah	Minimum of 110% of energy withdrawn	Good energy weight ratio; good charge retention; long wet-stand life	Expensive; poor low-temperature performance two step discharge curve
Zinc-air (oxygen)	Primary	$2Zn + O_2 + 4KOH + 2H_2O \rightarrow 2K_2Zn(OH)_4$ (large cells) $2Zn + O_2 \rightarrow 2ZnO$ (small cells)	Zinc	Oxygen	Aqueous solution of potassium hydroxide	1.25	80–100	3.2	Vented, $\frac{1}{2} - 2,000$ Ah	—	Flat voltage discharge characteristic; high input per unit volume in small cells	Drying out; carbonation, Water take up.
Lead-acid dioxide (usually called lead-acid)	Rechargeable	$2Pb + 2PbO_2 + 2H_2SO_4 + H_2O \rightleftharpoons PbSO_4 + 2PbO + 3H_2O$ $2Pb + 2PbO_2 + 2H_2SO_4 + H_2O \rightleftharpoons 2PbSO_4 + 2PbO + 3H_2O$	Lead	Lead dioxide	Aqueous solution of sulfuric acid	2.0	Sealed, 10–15 Vented, 7–12	0.8–1.1 0.5–2	Vented, 1—10,000 Ah	Over 100% of energy withdrawn	Low cost	Limited low-temperature performance; vented cells require sensitive, deteriorates if stored uncharged.
Nickel-cadmium	Rechargeable	$Cd + 2NiOOH + KOH + 2H_2O \rightleftharpoons Cd(OH)_2 + 2Ni(OH) + KOH$	Cadmium	Nickelic hydroxide	Aqueous solution of potassium hydroxide	1.25	Sealed, 12–17	Sealed 1–1.5	Sealed, 20 mAh–100 Ah	Sealed, minimum of 140% of energy withdrawn	Excellent cycle life; flat voltage discharge characteristic; good high- and low-temperature performance; high resistance to shock and vibration; can be stored indefinitely in any charge state	High initial cost; only fair charge retention. Reduced capacity over primary versions
							Vented, 12–20	Vented, 1–1.5	Vented–few Ah to over 500 Ah	Vented, minimum of 125-150% of energy withdrawn

TABLE 1. (*Continued*)

Battery System	Basic Type	Overall Chemical Reaction	Negative Electrode	Positive Electrode	Electrolyte	Nominal Voltage per Cell	Energy Density Watt-hours		Capacity	Input or Recharging	Advantages	Disadvantages
							Per Pound	Per Cubic Inch				
Lithium-iron sulfide	Primary solid cathode	$FeS_2 + 4Li \rightarrow Fe + 2Li_2S$	Lithium	Iron sulfide	Nonaqueous solution of lithium salts in ethers	1.0	—	—	38 mAh to 120 mAh	—	Good storage-ability ability; lower cost substitute for silver cells	Limited high rate capabilities, Complex manufacturing
Sulfur dioxide-lithium	Primary liquid cathode	$2SO_2 + 2Li \rightarrow Li_2S_2O_4$	Lithium	Sulfur dioxide	Nonaqueous solution of lithium bromide in mixture of SO_2 and acetronitrile	3.0	—	6–7	To 100 AH+	—	High energy and power densities; good storageability; good at low temperatures. Flat voltage.	Expensive. Complex manufacturing facilities required, and elaborate safety precautions
Primary Liquid Cathode	Thionyl Chloride Lithium	$2SOCl_2 + 4Li \rightarrow SO_2 + 4LiCl + S$	Lithium	$SOCl_2$ in $SOCl_2$	$LiAlCl_4$	3.5	—	11–14	To 100 AH+	—	High energy and power densities; good storageability; good at low temperatures. Flat voltage.	Expensive. Complex manufacturing facilities required, and elaborate safety precautions

*AH = ampere–hours; mAh = milliampre–hours. *Source*: Union Carbide Corporation.

The two electrodes are termed negative and positive here to avoid confusion that can result from use of the terms anode and cathode, the latter often being used loosely in the battery industry. The negative electrode of the primary (or charged secondary) cell is metallic and is oxidized (increased in valence) during discharge, giving up electrons to the external circuit. The positive electrode in an aqueous system initially is an oxygen donor, usually a metal oxide, which is reduced as it receives electrons from the external circuit. Charge transfer from one electrode to the other within the cell is via the ions of the electrolyte salt. In certain cells, the electrolyte enters further into reactions and actually changes in composition during use.

"positive" and that where the metal goes into solution, releasing electrons, is "negative." The electrons move from the negative to the positive by an external circuit doing work en route. Such a cell, however, is impractical for most uses, due to shortcomings, such as sensitivity to orientation, poor volumetric efficiency, rapid decay, gas formation, poor storability, and loss of electrolyte solvent. Thus, in practice, material that will go through a valence drop on electrochemical discharge is included in the positive electrode. Electrons coming from the negative electrode bring about this valence drop. This material is known as the *de-polarizer* and, in practice, all three states of matter, solid, liquid, and gas, are represented. When a solid, it is usually distributed as a powder to increase the surface area, through a conductive matrix which distributes the electrons, and the electrolyte is included to conduct the ions. The combination is known as the positive electrode and sometimes, simply as the cathode. A collector grid or rod joins it to the positive terminal of the battery.

The negative electrode, sometimes called the anode, contains the material that goes into solution as ions releasing electrons which do the work as they pass through the external circuit to the positive. It is most commonly a metal, but may also be other materials and in the form of a solid, liquid, or gas. Like the positive electrode, it may be combined with an electron collector matrix in a form that provides a high surface area. However, in systems where no solid product coats over the negative surface on discharge, solid anodes can be used in the form of sheet or foil and an additional electron collector may not be needed. The zinc can of the carbon zinc cell is an example.

Since the electrolyte is the ion transfer medium, it must be between the two electrodes as well as within them if they are porous. It can be liquid or solid, but because of the difference in ion mobility, the cells made with solids are usually only useful for low current drain applications. A barrier that will pass ions but not electrons, such as gels, wood, papers, porous plastics and ion exchange films, screens, beads, etc., is placed between the electrodes and designated as the separator.

Relatively few years ago, all the liquid electrolyte systems employed water as the electrolyte solvent, but in present practice, there are many non-aqueous systems in use. Thus cell systems are divided into two main categories — aqueous and non-aqueous. Electrolytes can be further subdivided into acidic, mildly acidic, and alkaline.

Aqueous Acidic Systems. The best-known example of this type is the lead sulfuric acid, rechargeable system in wide use for automobiles. In the car storage battery, the configuration is usually several flat plate electrodes per cell with negative and positive electrodes interspersed, separated by ion-permeable plastic, wood, or other stable materials to give a high electrode interface area. The electrolyte is not immobilized — so this is a wet rather than dry cell. For present-day automobiles, which operate on 12 volts nominal, six cells are connected in series per battery. A typical automobile lead-sulfuric acid storage battery is shown in Fig. 1. This system is also marketed in dry-cell designs and small sizes utilizing designs similar to those described for nickel cadmium alkaline cells, i.e., "jellyroll" in cylindrical cells and flat plate electrodes in prismatic containers.

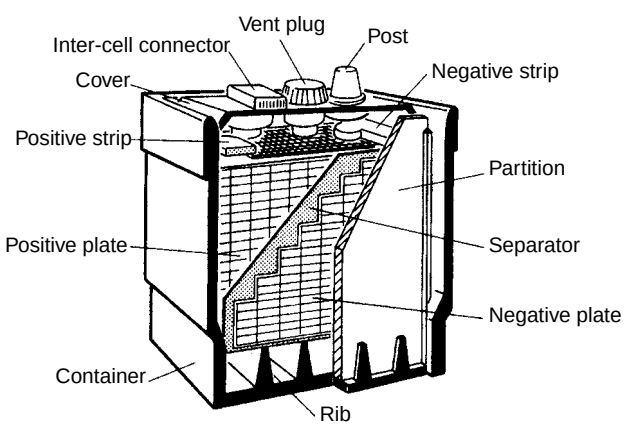

Fig. 1. Cutaway view of automotive-type storage battery.

Specialty batteries as for golf carts, which require deep discharge capabilities, use special lead alloys, and the need to add water to replace that lost on charge in the lead acid batteries has been virtually eliminated by using catalysts to recombine chemically the hydrogen and oxygen formed by charging inefficiency.

Aqueous Mildly Acidic Systems. Probably the best-known of this type is the cylindrical carbon/zinc cell, which once used only the Leclanche system, a mixture of ammonium chloride and zinc chloride in water as the electrolyte solute. This now includes the zinc chloride system, which has little or no ammonium chloride. The latter are usually heavy duty, as opposed to light duty for the Leclanche. The Leclanche cells also usually use MnO_2 ores while the $ZnCl_2$ use synthetic MnO_2. The Leclanche is therefore usually lower in cost. At one time most cell designs used starch gels as the separator but there has been a steady shift to coated paper in order to increase the fill efficiency. A cylindrical cell design is illustrated in Fig. 2.

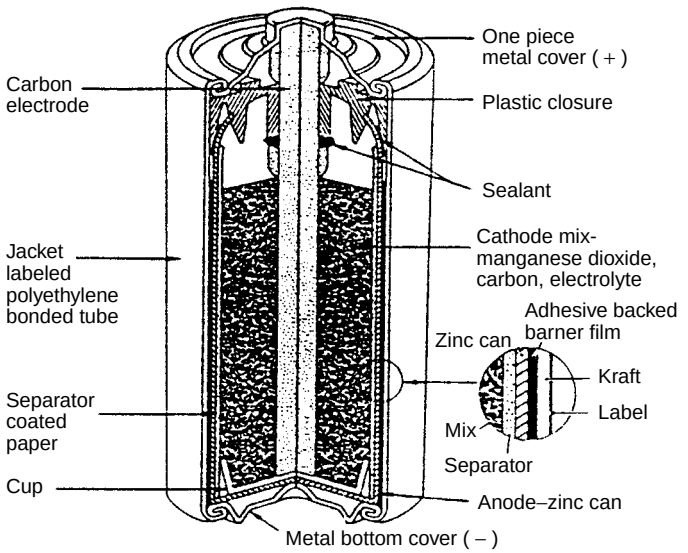

Fig. 2. Round carbon-zinc cell. (*Eveready Battery Company Inc.*)

Other mildly acid systems using MnO_2 as the cathode and other anode metals and electrolyte salts are: magnesium cells, with aqueous magnesium perchlorate or bromide as the electrolyte and magnesium alloy as the negative electrode; aluminum cells, with aluminum salts as the solute and aluminum alloy anode; and low-temperature cells, which use electrolytes that have low freezing points such as magnesium chloride and lithium chloride. The designs are similar to the ones used with the Leclanche and zinc chloride systems, and the cells are used for special applications, mostly military.

Aqueous Alkaline Systems. The majority of these systems use potassium hydroxide as the electrolyte solute, but some use sodium hydroxide. Potassium hydroxide imparts higher rate capabilities, but sodium hydroxide is cheaper and easier to contain and sometimes imparts better storability. The aqueous alkaline systems, as a rule, have higher rate capabilities, better low-temperature performance, and higher energy densities than the aqueous, mildly acidic cell designs. However, the cell designs using this system are usually more complex and costly.

Aqueous alkaline systems are used in wet and dry cells and in secondary as well as primary batteries. An example of a secondary dry cell is the "jellyroll" cylindrical, "nickel-cadmium" rechargeable battery shown in Fig. 3. An example of a primary dry cell is alkaline MnO_2/Zn cell shown in Fig. 4.

As the size of batteries becomes relatively small, such as for use with electric wristwatches, the cost of the materials becomes a smaller proportion of the total cost, since assembly costs remain relatively constant. Systems that yield a high output per unit volume of cell, even if made with expensive materials, become preferable. Silver oxide/zinc is a good example. The miniature cell designs for several of the systems now marketed, i.e., MnO_2/Zn, Ag_2O/Zn, AgO/Zn, HgO/Zn, CuO/Zn, and air/Zn, MnO_2/Li, CF_x/Li etc. are quite similar. A typical miniature, sometimes called "button," silver oxide cell is shown in Fig. 5. The larger the cell, the more important the cost of the materials. Thus, in flashlight battery sizes, the MnO_2/Zn system is most common in the marketplace.

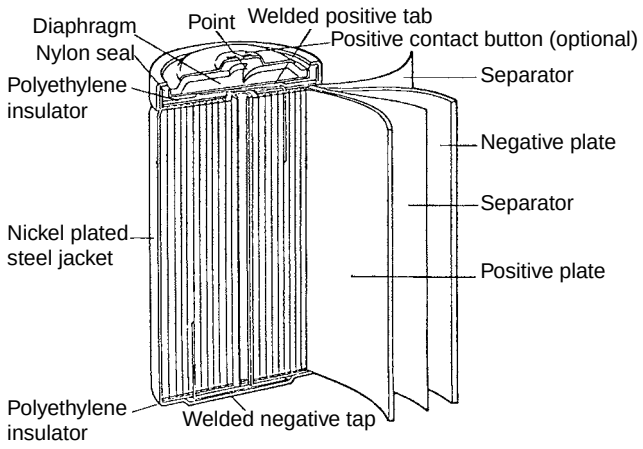

Fig. 3. Cutaway view of sealed, coiled-type, sintered nickel-cadmium cell.

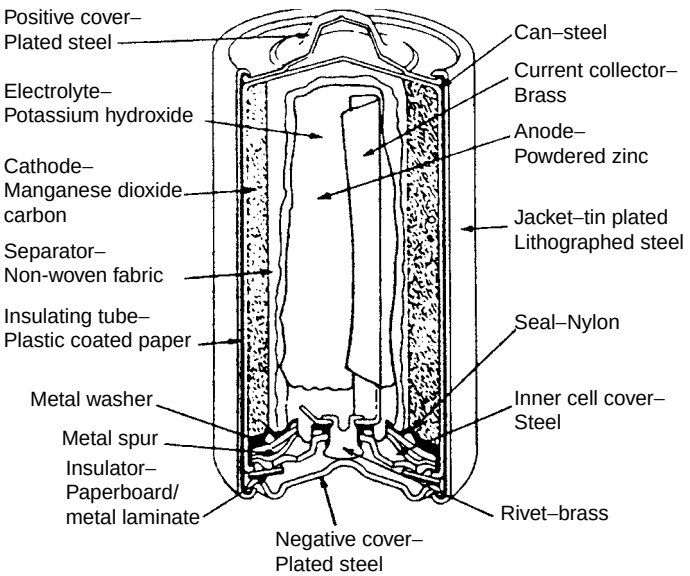

Fig. 4. Cutaway view of cylindrical alkaline cell.

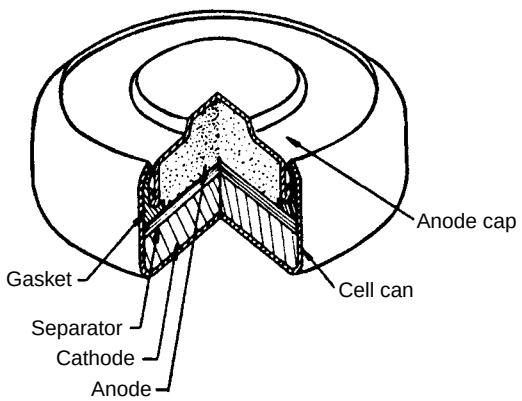

Fig. 5. Silver oxide cell.

Large cells using costly electrochemical systems are limited to special applications, such as in space, or geological studies.

Gas Electrodes. Good examples of the wide variety of systems of this type being used or being considered for future use are the air-zinc and chlorine-zinc cells. Both of these cells use a gas as the positive electrode-active material. The first is an alkaline aqueous system, which uses oxygen from the air, activated on a special material, to act as the oxidant or depolarizer. Button air cells for special applications, recently introduced to the market, provide significantly higher volumetric energy densities than some

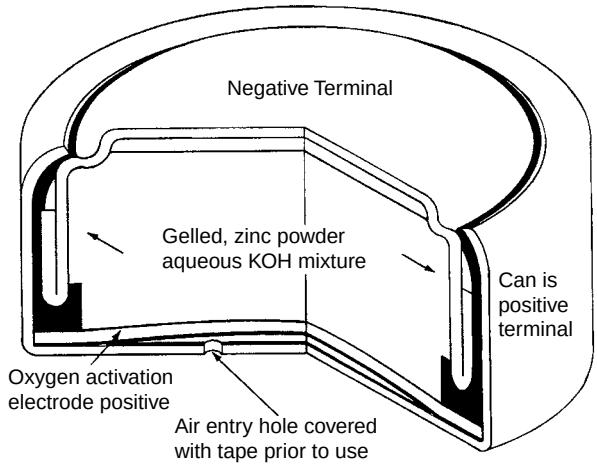

Fig. 6. Miniature air depolarized battery.

of the systems marketed earlier. Figure 6 illustrates how this differs from the solid de-polarizer cell of Fig. 5. The second is a mildly acidic aqueous system being considered for rechargeable batteries in electric cars and load-leveling in electric power generation. Chlorine is combined with zinc to a salt at an activating electrode on discharge and formed as a gas to be transported to and stored in another location as a solid hydrate, on charge.

Non-aqueous Batteries. These cover almost as wide a range as do the aqueous systems. They employ active metals that are incompatible with water, and thus must be water free — hence the term *non-aqueous*. A relatively few years ago, non-aqueous batteries were unknown in the marketplace, but rapid strides have been made in recent years, due to the need for better storability, higher energy densities, better performance at very low temperatures and, in some cases, such as to replace silver oxide cells, alternatives to increasing costs of materials. The higher a metal on the electromotive (activity) series, the higher the voltage versus a given positive electrode and, therefore, the higher the watt-hours (Wh) for the same ampere-hours (Ah). With water-free systems, metals such as lithium, sodium, calcium, and magnesium, which are more negative than systems compatible with water can be used. To date, all the non-aqueous systems reaching the market use lithium as the anode.

Positive electrode materials under consideration cover a wide range of voltages. Where the battery must be substitutable for a currently available aqueous system single cell, a low-voltage match must be used. Examples are PbO, CuO, FeS, and FeS_2 versus Li. These are all solid de-polarizers. For existing or new high-voltage applications, MnO_2 and fluorinated carbon are being used as solid de-polarizers, and SO_2, SO_2Cl_2 and $SOCl_2$ are being used as liquid cathodes. The latter two have the advantage of being good solvents for the needed salt and discharge to another liquid that can take over as the electrolyte solvent. Therefore, they serve a dual role as cathode and electrolyte solvent. They are active only on a special activating electrode surface — so they do not combine directly with the lithium anode. The solid de-polarizers all require non-reacting solvents in the electrolyte, and most are organics.

A cylindrical cell design utilizing the SO_2Cl_2/Li system, which is a liquid cathode type, is illustrated in Fig. 7. The electrolytes using $SOCl_2$ and SO_2Cl_2 in the dual role have good ionic mobility and therefore cells of low positive to negative interface areas can handle moderate drains. Organic solvents, however, give electrolytes of low ionic mobility and cells using them are either low rate or depend upon high positive to negative interface area designs, such as “jellyroll,” to handle moderate to high rates.

Some use a molten salt as the sole transporter of ions; no solvent is used. The thermally activated reserve cells are such. Some work with the salt as a solid, and therefore are known as solid electrolyte systems. However, the ion mobility in these solid salts is very poor and therefore they are applicable only for low current discharges that extend over years. Such an application is heart pacemakers and an example system is iodine/lithium. Lithium iodide formed chemically on the lithium serves as the separator and as the ion carrier. A thin miniature cell is the favored design.

Several non-aqueous systems are being investigated for high-energy density rechargeable batteries. Some are thermally activated, i.e., salt is heated to the melting point to form a liquid electrolyte. This usually means that the lithium or sodium, usually used for the anodes, are also molten. The

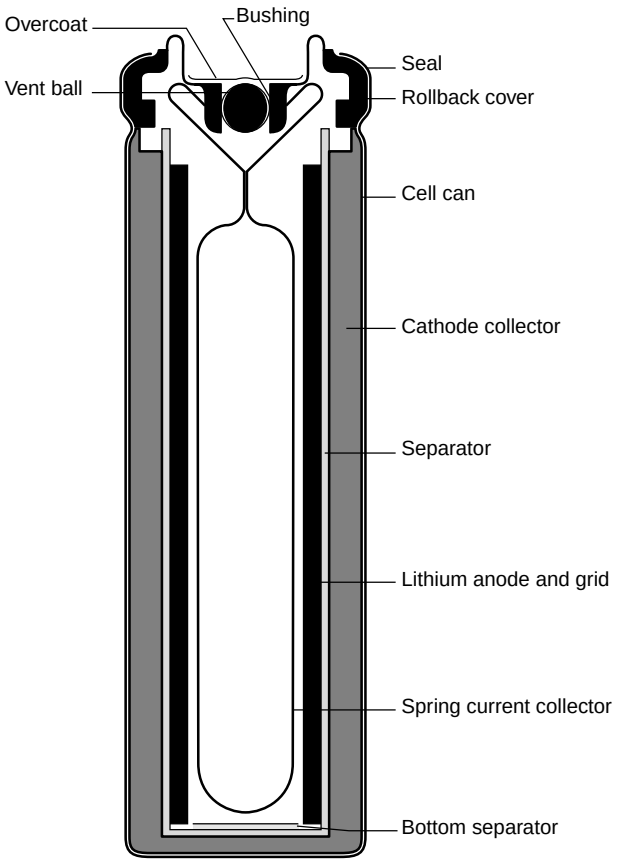

Fig. 7. Moderate rate lithium/$SOCL_2$ cell.

operating temperatures are high, such as 300 °C, and thus unique design and operating problems must be solved.

Water is a contaminant for non-aqueous systems and, therefore, special environments for cell assembly are required. These add significantly to the cost.

Summary. Some of the systems used in commercially available batteries are described in Table 1. The table is abridged and included mainly to illustrate the present diversity in battery technology.

Standard Cells

Primary cells are also used as standards of electromotive force (emf) and are suitable for precise measurements, such as those made with a potentiometer which requires a constant, known emf. Over the years two principal standard cells have been used, the Clarke cell and the Weston cell. The Clarke cell has a mercury cathode and an amalgamated zinc anode. The cathode is submerged in a mercurous sulfate paste, and the electrolyte is a solution of zinc sulfate saturated at 0 °C. The system is sealed in a glass tube and develops an emf of 1.440 volts at 15 °C with a decrease of 0.00056 volt per °C rise in temperature. The Weston standard cell, a diagram of which is given in Fig. 8, is made in two types, the normal cell containing a saturated cadmium sulfate solution and another type which is used as a working standard in which the solution is less than saturated above 4 °C. The saturated cell is the basic standard for maintaining the value of the volt, and is used in this manner in national standards laboratories. Its rather high temperature coefficient must always be taken into account. The legal voltage of the standard-cell group in the United States is 1.018636 volts absolute at 20 °C and this value is accepted by international agreement.

The emf of the unsaturated Weston cell is within 1.0188 to 1.0198 volts absolute, with the exact voltage of each cell being established by comparison with the normal or saturated cell. The unsaturated cell is a useful working standard because of its negligible temperature coefficient.

BAT TICK *(Insecta, Diptera)*. Highly specialized flies that live as ectoparasites on bats. Like other parasitic flies, their habits are accompanied by some structural resemblance to the true ticks, hence the inaccuracy of the common name. The bat ticks belong to two families, *Streblidae* and *Nycteribiidae*. All species of the latter are wingless.

BAUD. A baud is the unit of telegraph signaling speed, derived from the duration of the shortest signaling pulse. A telegraphic speed of one baud is one pulse per second. The term "unit pulse" is often used for the same meaning as the baud. A related term, the "dot cycle," refers to an on-off or mark-space cycle in which both mark and space intervals have the same length as the unit pulse.

BAUDOT CODE. A teleprinter code that uses combinations of five and six marking and spacing intervals of equal duration. The five-unit code gives 32 possible characters; and the six-unit code gives 64 possibilities. The code is used in radio and wire teleprinter operations.

BAUME SCALE. See **Specific Gravity**.

BAUXITE. There are two main types of bauxite ores used as the primary sources for aluminum metal and aluminum chemicals: $Al(OH)_3$ (gibbsite) and AlO(OH) (boehmite). Thus, bauxite is a term for a family of ores rather than a substance of one definite composition. The first bauxite ore was found near Les Baux in the south of France by P. Berthier (1821). Deposits are found worldwide except in Antarctica. Secondary sources of aluminum include a large array of clays that are rich in alumina (30–40%) found in large abundance throughout the world. Bauxite ores range in color from white to dark red or brown, largely depending upon the iron content. An average composition of the ores used by industry today would be: Al_2O_3, 35–60%; SiO_2, 1–15%; Fe_2O_3, 5–40%; TiO_2, 1–4%, H_2O; 10–35%; other substances, 0–2%.

Although developed as early as 1888 by the Austrian chemist, Karl Josef Bayer, the Bayer process still is used almost exclusively for the extraction of alumina from ores. The bauxite first is reacted under pressure with hot caustic, which dissolves the $Al_2O_3 \cdot xH_2O$ to form sodium aluminate. The solution is filtered hot, then cooled and agitated with the addition of a small quantity of aluminum hydrate to enhance the precipitation of the crystalline hydrate. After filtration, the cake is kiln-dried at 1100 °C to remove H_2O and yield Al_2O_3.

The purity of aluminum produced by the electrolytic process (see **Aluminum**) is determined mainly by the purity of the Al_2O_3 used. Thus, commercial grades of Al_2O_3 are 99–99.5% pure with traces of H_2O, SiO_2, Fe_2O_3, TiO_2, ZnO, and very minute quantities of other metal oxides.

As of 1991, there were nine alumina plants in the United States and territories. Six plants were located on the Gulf Coast, two plants were in Arkansas, and one plant was in the Virgin Islands. Total capacity was estimated at 7.7 million short tons (approximately 6.9 million metric tons). The aluminum industry in the United States has depended on imports from the Caribbean, South America, and Australia. Caribbean exporting countries have high levies on bauxite exports and, politically, have moved to nationalize and expropriate the bauxite mines developed by United States industry. It is doubtful that new Bayer alumina plants will be built in the United States. The technology in the United States is focusing on extracting alumina from abundant alumina-containing clays, but these programs are being de-emphasized because of great new bauxite finds. New Bayer plants in Australia and Venezuela will be key future suppliers.

The industry has maintained a continuous exploration program, which has been very successful. There has been a fivefold increase in world reserves of bauxite since 1965; at that time the world reserves were 6 billion tons, whereas in 1981 there were 29 billion tons in reserve. The source of that information is the *J. of Metals*, February 1986, page 19, article by A.S. Russell, "Aluminum Technology Responds to Change."

Uses and Grades of Alumina. Although aluminum production is a major consumer of alumina, the compound is used widely elsewhere. The properties of alumina and hydrated aluminas may be varied, ranging from a talc-like softness to the hardness of a ruby or sapphire. Some of the uses for alumina include water purification, glassmaking, production of steel alloys, waterproofing of textiles, coatings for ceramics, abrasives and refractory materials, cosmetics, and electronics. *Hydrated aluminas* may be represented: α-$Al_2O_3 \cdot H_2O$ or α-$Al(OH)_3$. The compounds are dry, snow-white, free-flowing crystalline powders and may be obtained in a wide range of particle sizes. The compounds are widely used in the production of aluminum salts because of their reactions with strong acids and alkalies. Some of the salts prepared in this manner include aluminum chloride, aluminum phosphate, and aluminum sulfate. *Activated aluminas* are very porous aluminum oxide. λ-Al_2O_3 is made by heating the hydrate to drive off nearly all of the combined water. The final products are granules or fine powders with a large surface area to provide absorptive capacity per unit volume. Applications of the aluminas are enhanced by virtue of their chemical inertness and nontoxic qualities. They are extensively used for drying gases and for dehydrating liquids, such as alcohol, benzol, carbon tetrachloride, ethyl acetate, gasoline, toluol, and vegetable and animal oils. They also are used as filter aids in the manufacture of lubricating and other oil products. Their large surface area qualifies the aluminas as catalysts for numerous reactions. The compounds also find extensive application in ceramics, particularly in abrasive and cutting wheels, polishing compounds, additives to glass, tank linings, spark plugs, electrical substrates, and linings for high-temperature furnaces.

Alumina fibers for composites with metal and plastics are under development as are structural ceramic products, including engine components. Fine, specialty grades of alumina are also used in toothpaste.

Corundum is an aluminum oxide that possesses a hexagonal crystal structure. The compound is extremely hard (2000 on the Knoop scale), sp gr 3.95, and is widely used in abrasives and refractories. Corundum is manufactured by fusing alumina or bauxite in an electric arc furnace operated at about 2200 °C.

BAYBERRY SHRUBS AND TREES. Of the family Myriaeceae, *genus Myricia*, there are three species of bayberry of interest. The *M. carolinensis* is found near the seashore from the West Indies and Florida northward to Prince Edward Island and New Brunswick. Normally, the plant may be described as a compact shrub that prefers dry, sandy, and rocky soil. However, it does occur in some of the bogs of northern New Jersey and Pennsylvania and also is found along the shore of Lake Erie. The berry occurs in crowded clusters. The berry is small, approximately $\frac{3}{16}$ inch (0.5 centimeter) in diameter, of a grayish-white color, and is waxy and resinous. The plant has long, fragrant leaves. Candles can be made from the berries. They are boiled and the waxy substance is skimmed off, after which it is melted and refined. The yield of wax is quite good, approximately 25% of the weight of the raw berries representing wax. At one time used by the settlers, the candles now are mainly associated with the Christmas holiday and are noted for a distinctive, pleasant aroma.

Also known as wax myrtle or bayberry, the *M. cerifera* is a small tree, slender of contour, that prefers sandy swamps of the southern states and coastal plains. The tree is found from Florida northward into southern Maryland and westward to the Gulf States. See Table 1. This species also has small, grayish-white berries, even smaller than the *M. carolinensis*.

Also known as the California wax myrtle or bayberry, the *M. californica* is a small tree with smooth, grayish bark and branches. The tree is slender in contour, with a rounded crown. The berries are similar to those of *M. cerifera*, slightly larger, and of a dark purple coloration, but like the other bayberrys, covered with a white waxy material. The tree prefers coastal areas, such as damp slopes and sand dunes. It is found from southern California northward to Oregon. See Table 1.

Other members of the *Myriaeceae* family (sometimes called Sweet Gale family) include *M. Gale* (Sweet Gale or Dutch Myrtle), a small shrub attaining a height of about 5 feet (1.5 meters) and essentially similar to the bayberrys. However, it is distributed much more widely, preferring the edges of ponds, swamps, and streams, from Labrador and Newfoundland west to the Great Lakes and northwestward to Alaska. The shrub is found in the Appalachian Mountains to the 3000-foot (900 meter) level as far south as Virginia. It is also relatively common throughout most of New York and New England. *M. asplenifolia* (sweet fern) has a nutlike fruit which, as well as the leaves, is fragrant when crushed. The shrub seldom exceeds 2 feet (0.6 meter) in height and is found in dry areas, and ranges from New Brunswick and Nova Scotia westward to Alberta and south as far as North Carolina. It is found in the White Mountains and in the Alleghany Mountains up to the 2000-foot (600 meter) level. *M. inodora* (odorless myrtle) is considerably less common than the other trees and shrubs described previously. The plant ranges in height from 5 to 18 feet (1.5 to 5.4 meters), with a grayish-white bark and leathery leaves of a deep green color. The berries are over 1/4 inch (0.6 centimeter) in diameter, grayish white in color, and covered with a white wax. The plant also likes the edges of ponds and swamps and coastal climes, ranging from Florida westward to Mississippi.

TABLE 1. RECORD BAYBERRY TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Northern bayberry (1999) (*Myrica pensylvanica*)	10	25.4	13	3.96	10	3.05	North Carolina
Odorless bayberry (1994) (*Myrica inodora*)	33	83.8	18	5.49	23	7.01	Alabama
Pacific bayberry (1999) (*Myrica californa*)	46	117	38	11.6	35	10.7	California
Southern bayberry (1993) (*Myrica cerifera*)	68	173	28	8.53	33	10.1	North Carolina
Southern bayberry (1994) (*Myrica cerifera*)	76	193	20	6.1	38	11.6	Virginia
Southern bayberry (1994) (*Myrica cerifera*)	72	183	25	7.62	36	11	Virginia
Southern bayberry (1994) (*Myrica cerifera*)	68	173	26	7.92	32	9.75	Virginia

[2]At 4.5 feet (1.4 meters).

The *M. cerifera* and *M. carolinensis*, previously described, as well as *M. mexicana* (grown in Mexico and Central America) and *M. ocuba* (grown in Brazil) are commercial sources of products known as vegetable tallow, bayberry tallow, myrtle wax, and ocuba wax. Ocuba wax is classified as a waxy fat, not truly a wax in the chemical sense.

BAYER DESIGNATION. Many of the brighter stars are given names which are known as "Bayer designations." These designations, which were introduced by Johann Bayer in his star atlas *Uranometria* (named after Urania) in 1603, consist of a Greek letter followed by the genitive (in Latin) of the name of the constellation in which the star lies. They were generally named starting with the brightest star and continuing to the dimmest of any given constellation.

Because the brightest star in many constellations is designated as Alpha, many people wrongly assume that Bayer meant to put the stars in order of their brightness. But in his day there was no way to measure stellar brightness precisely. Traditionally, the stars were assigned to one of six magnitude classes, and Bayer's catalog lists all the first-magnitude stars, followed by all the second-magnitude stars, and so on. However within each magnitude class, there was no attempt to arrange stars by relative brightness. Instead, they're usually either roughly ordered from the head to the feet (or tail) of the figure (like the stars in the Big Dipper).

Orion provides a good example of Bayer's method. (Remember that the *lower* the magnitude, the *brighter* the star. Additionally a "2nd-magnitude" star has a more precise magnitude between 1.51 and 2.50, inclusive.) Bayer first designated the two 1st-magnitude stars, Betelgeuse and Rigel, as Alpha and Beta, with Betelgeuse (the shoulder) coming ahead of Rigel (the knee), even though the latter is the brighter. See also **Apparent Magnitude**.

There are two common ways in which Bayer designations can be written. The designation can be written out in full, as in Alpha Canis Majoris or Beta Persei, or a lowercase Greek letter can be used together with the standard 3-letter abbreviation of the constellation, as in α CMa or β Per. Earlier 4-letter abbreviations (such as α UMaj) are rarely used today.

Although most common Bayer letters are Greek, it should also be mentioned that the system was extended, first by using lowercase Latin letters, and then by using uppercase Latin letters. Most of these are little used, but there are some exceptions such as h Persei (which is actually a star cluster) and P Cygni. Note that uppercase Latin Bayer designations never went beyond Q, and names such as R Leporis and W Ursae Majoris are variable star designations, not Bayer designations.

A further complication is the use of numeric superscripts to distinguish between stars with the same Bayer letter. Usually these are double stars (mostly optical doubles rather than true binary stars), but there are some exceptions such as the chain of stars π^1, π^2, π^3, π^4, π^5 and π^6 Orionis.

BAYER PROCESS. Process for making alumina from bauxite. The main use of alumina is in the production of metallic aluminum. Bauxite is mixed with hot concentrated sodium hydroxide, which dissolves the alumina and silica. The silica is precipitated, and the dissolved alumina is separated from the solids, diluted, cooled, and then crystallized as aluminum hydroxide. The aluminum hydroxide is calcined to anhydrous alumina, which is then shipped to reduction plants.

BAY (Laurel) LEAVES. See **Spices**.

BAYLISS, WILLIAM MADDOCK (1860–1924). William Bayliss was an English physiologist who investigated the physiology and biochemistry of intestinal and pancreatic function, discovering with his brother-in-law Ernest Starling the digestive hormone secretin; he also formulated an effective treatment for wound shock during World War I. Bayliss was born and educated in Wolverhampton, moving with his family to London in 1880, where he started studying medicine at University College, London. Disliking, and failing, anatomy, he abandoned plans for a medical career, and moved to Oxford to study physiology under John Burdon Sanderson, graduating with a first class honours degree in 1888. He immediately returned to University College, where he remained for the rest of his life, becoming Professor of General Physiology in 1912.

With Starling, Bayliss worked on a wide range of physiological problems, including the electrical activity of the heart, the innervation and control of the heart and circulation, and pancreatic secretion. They showed that an excitatory substance released from cells in the duodenum, in response to the presence of food, travelled in the circulation to stimulate the pancreas to liberate digestive juices. They called this chemical secretin, and coined the word 'hormone' to describe it and similar substances, thus opening up the new research field of endocrinology. Also with Starling, Bayliss further investigated the enzymatic actions of pancreatic juice, work which led Bayliss to study enzyme action in terms of chemical and physical interations. His interest in the physico-chemical basis of biological processes prompted work on the properties of colloids and osmotic pressure, which had immediate practical application during World War I, when as a member of a Special Investigation Committee on Surgical Shock, he suggested giving soldiers suffering from wound shock an infusion of gum acacia and saline, which at the time provided an acceptable treatment, since superseded by blood transfusion. See also **Starling, Ernest Henry (1866–1927)**.

As an author, Bayliss' great achievement was *Principles of General Physiology*, the first edition of which appeared in 1915, and which continued under the editorship of his son until 1960. The volume examined physiological function in terms of the underlying principles of chemistry and physics, and such was the attention that it received, that a number of 'Bayliss clubs' were established in American universities just after World War I specifically to discuss the book. See also **Physiology (The History)**.

BAYOU. A stagnant or abandoned course of a meandering river. Also a general term for a stagnant inlet or outlet of a lake or bay. See **Ox Bow Lake**.

BAY TREE. See **Laurel Family**.

B COMPLEX VITAMINS. See **Vitamins**; **Vitamin B_6 (Pyridoxine)**; and **Vitamin B_{12} (Cobalamin)**.

BDELLOIDEA. An order of rotifers, named for their fancied resemblance to leeches in their looping method of progression.

BDELLONEMERTEA. An order of nemertine worms of broad, flat form, named from their superficial resemblance to leeches. They live in the branchial chamber of mollusks.

B-DISPLAY. In radar, a rectangular display in which targets appear as blips with bearing indicated by the horizontal coordinate and distance by the vertical coordinate. Also called *B-scan* or *B-scope*.

BEACON DELAY. The amount of inherent delay within a beacon, i.e., the time between the arrival of a signal and the response of the beacon.

BEACON SKIPPING. A condition where transponder return pulses from a beacon are missing at the interrogating radar. Beacon skipping can be caused by interference, overinterrogation of beacon, antenna nulls, or pattern minimums.

BEADLE, GEORGE WELLS (1903–1989). Beadle was an American geneticist who, with Edward L. Tatum demonstrated the genetic control of enzyme synthesis whereby the production of each enzyme is controlled by a different gene: the 'one gene–one enzyme' theory.

Beadle was born in Wahoo, Nebraska, and the son of a successful farmer. At the University of Nebraska, College of Agriculture he gained BSc and MSc degrees. Rather than return to the farm in 1927 he went to Cornell University to study the genetics and cytology of maize under R. A. Emerson. Beadle left Cornell in 1931 with a PhD to take up post-doctoral work with T. H. Morgan at Caltech. After finishing some work on maize genetics, Beadle turned his attention to learning about *Drosophila*. In retirement he would return once more to maize, researching the transition from wild grass to cultivated food plant.

In 1934 Boris Ephrussi joined Beadle at Caltech. The Frenchman was skilled at tissue culture and transplantation and shared Beadle's interest in gene action. The two men returned to Ephrussi's laboratory at the Institut de Biologie in Paris where they formulated a series of experiments transplanting eye buds from one *Drosophila* larva to another. From their results, detectable as different eye colors, they hypothesized that development of such physical features could be interpreted as a series of chemical reactions, each stage of which was under genetic control. However, the *Drosophila* model would prove too complicated in experimental terms despite five years of painstaking work to determine the chemical basis of the eye color pigments.

Beadle returned from France to an assistant professorship at Harvard in 1936 and moved a year later to a professorship of biology at Stanford University. Here he formed another crucial collaboration, this time with the biochemist Edward L. Tatum. Tatum worked on the biochemistry of *Drosophila* eye color pigments, but it was for their joint work on the red bread mould, *Neurospora crassa*, that Beadle and Tatum would take a half share of the Nobel Prize in Physiology or Medicine for 1958 (Joshua Lederberg was the other winner).

In addition to its faster life cycle and ability to reproduce asexually and sexually, *Neurospora* has experimentally exploitable nutritional habits. Able to grow on a very basic food medium, the mould has an enzyme system that allows it to synthesize most of the proteins and vitamins needed for growth. Irradiated cultures of *Neurospora* carried mutant genes, which meant certain amino acids (the building blocks of proteins) could not be formed, although the mutants were sometimes able to use a similar compound to produce the missing amino acids. Beadle's analysis of these results led to his understanding the metabolic pathways involved in protein synthesis. Further analysis of crossed strains of mutants revealed the individual genes responsible for each stage of the synthesis. Beadle and Tatum proposed the one gene–one enzyme theory and this shifted the emphasis of genetics research in the 1940s from an organism's physical characteristics to its biochemistry.

Beadle succeeded Morgan as head of the Biology Division at Caltech in 1946. A year earlier Tatum had left for Yale where he continued to work with Lederberg on bacterial genetics. Beadle was an able administrator. He took on the difficult task of trying to rejuvenate the University of Chicago, struggling with the problems of urban decay, while serving as chancellor from 1961 until retirement in 1968.

H. J. POWER, Wellcome Trust Centre for the History of Medicine at UCL, London, UK

BEAM (Composite). A beam composed of two materials properly bonded together and having different moduli of elasticity is called a composite beam. Reinforced concrete beams, steel beams mechanically bonded to a concrete deck, and wood beams reinforced with steel plates are typical examples. It has become a rather prevalent practice in recent years to provide for composite action between the steel stringers and concrete floor of highway bridges. This permits the use of lighter beams than would otherwise be possible.

The analysis of composite beams depends on the assumption that a plane section before bending remains plane after the load is applied. Therefore the two materials must be connected in such a way that they will act as a unit. This condition is realized in the reinforced concrete beam by means of the bond (see **Stress (Structural)**) between the reinforcing rods and the concrete. In the case of reinforced wood beams the parts are connected by bolts properly spaced to resist the shearing forces (see **Shear**) between the plates and the beam. Steel beams are bonded to the concrete flange by means of lugs or spirals welded into the top flange of the steel beam.

The flexure formula is applicable to composite beams if the beam is transformed into an equivalent homogeneous section by means of the transformed area method, which is found in texts on strength of materials and reinforced concrete design.

BEAM (Structural). Beams used for building various structures, such as bridge decks and flooring, building floors and roofs, and other applications where support over a span of distance is required, may be classified in a number of ways: (1) by cross sectional shape, such as the familiar I-beam of steel or the rectangular section of a wood beam, (2) by the material from which the beam is made, and (3) by the manner in which the beam is used, that is, the structural design configuration (method of support).

Decks, floors, and roofs often are supported on a rectangular grid made up of flexural members. Commonly, the members which provide the span between main supports are termed *girders*, essentially large heavy beams capable of carrying concentrated as well as evenly distributed loads. See also **Girder**. Beams that rest across a series of girders are simply termed *beams*. See Fig. 1. The type of framing shown is commonly referred to as *beam-and-girder* framing. Special nomenclature is frequently applied for specific applications. The parallel (to flow of traffic) structural members of a bridge sometimes are called *stringers*. The transverse members supporting the floor or deck may be called *floor beams*. The grid components for a building roof often are referred to as *purlins* and *rafters*, whereas in floor supports, they may be termed *joists* and *girders*. Most frequently, beam-and-girder framing is employed for rather short spans where shallow members are desired for allowing ample headroom underneath.

The six most common methods of beam support are illustrated in Figures 2 through 7.

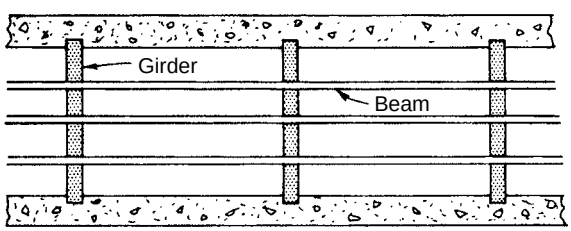

Fig. 1. Beam-and-girder framing.

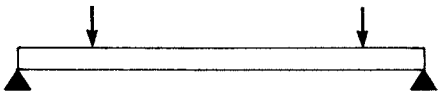

Fig. 2. Simple beam

Fig. 3. cantilever beam.

A *simple beam* (Fig. 2) is one which rests on two end supports in such a manner that the ends of the beam are free to rotate on the supports. The supports restrain the beam only against vertical movement. To allow for a horizontal component and also for change in length arising from a temperature change, the supports may have to prevent horizontal motion, usually accomplished by providing a horizontal restraint at one support. The term *span* is used to designate the distance between supports. The term *reaction* designates the load carried by each support.

A *cantilever beam* (Fig. 3) is a beam that is rigidly connected at one end to a fixed support and free to move at the other end. This theoretically fixed condition rarely occurs because of deformation of the supporting material. The maximum bending moment and maximum shear occur simultaneously at the face of the support. The usefulness of this type of beam is demonstrated in structures, such as canopies, unbraced airplane wings, and cantilever retaining walls. A support of this type is called a *fixed end*.

A beam with *one end fixed* (Fig. 4) results when a support is placed under the free end of a cantilever beam.

A *fixed-end beam* (Fig. 5) permits no rotation or vertical movement. In practice, a configuration of this type can seldom be obtained. The majority of support conditions fall intermediately between those applying for a simple beam and those for a fixed-end beam.

A beam with *overhangs* (Fig. 6) has supports that permit rotation, but the overhangs have a free end.

A *continuous beam* (Fig. 7) is a beam having more than two supports. A beam that is continuous over several supports offers more difficulty in analysis than would a series of freely supported beams covering the same overall span. However, it can be analyzed readily by methods, classical or numerical, available for the analysis of statically indeterminate structures. Because of the restraint at the intermediate supports, the continuous beam can carry a greater load than a simple beam of the same size and span. It is quite important to provide a firm foundation for the intermediate supports, as small deflections due to sinking of an intermediate support may introduce stresses of an entirely different nature and magnitude from those used in designing the beam.

A curved beam is a beam having a finite radius of curvature before and after the bending loads are applied. Theoretically the flexure formula is not

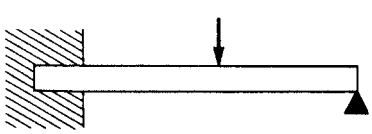

Fig. 4. Beam with one end fixed.

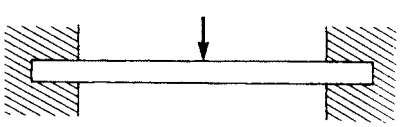

Fig. 5. Fixed-end beam.

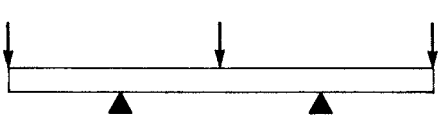

Fig. 6. Beam with overhangs.

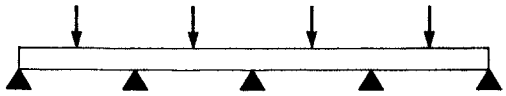

Fig. 7. Continuous beam.

applicable to curved beams because the unit deformation does not have a straight-line variation over the depth of the beam due to the difference in the length of the various fibers between any two radial planes. Formulae for curved flexural members are given in texts on advanced strength of materials. Reliable values of extreme fiber stresses may be found by means of correction factors, applied to the flexure formulas, which are also in these texts. The correction factor depends on the radius of curvature and the shape of the cross section. However, a member must have a considerable amount of curvature before there is an appreciable difference between the stresses found by the straight beam (flexure) theory and the curved beam theory. Consequently a correction factor of 1 is frequently used when the radius of curvature is large.

The curved beam theory or a modification of this theory should be applied to the analysis of any curved flexural member of small radius of curvature even though the member cannot be classed as a beam. Hooks and chain links are typical examples.

See also **Bending Moment**.

BEAM SWINGING. A technique used by wind profilers to determine the vertical profile of the wind vector above the radar by measuring the line-of-sight component of the wind sequentially along each of several different beam directions. The different beam directions can be obtained in various ways: 1) mechanically steering a single fixed-beam antenna; 2) electronically or mechanically steering the beam of a single fixed-position antenna; or 3) switching between multiple fixed-beam antennas. See also **Antenna (Communications)** and **Winds and Air Movement**.

Three beam positions can be used to determine the wind vector if it is assumed that the wind field is the same along those beams. At least five beam positions must be used to measure both the wind and its divergence. Wind profilers typically use one vertical beam and oblique beams that are between 10° and 25° off vertical. Oblique angles closer to the zenith make separation of horizontal and vertical wind components difficult and larger zenith angles make it less likely that the wind is uniform over the horizontal distances between beams. Large zenith angles also increase the radial range to the scattering volume at a given altitude, thereby reducing the strength of the returned signal.

AMS

BEAM WIDTH. A measure of the concentration of power of a directional antenna. It is the angle in degrees subtended at the antenna by arbitrary power-level points across the axis of the beam. This power level is usually the point where the power density is one-half that which is present in the axis of the beam at the same distance from the antenna (half-power points). Also called *beam angle*.

The beam width of a radar determines the minimum angular separation which two targets can have and still be resolved. Roughly speaking, two targets at the same range whose angular separations at the radar antenna exceeds one-half of the beam width between half-power points will be resolved or distinguishable as two individual targets. The smaller the beam width, the greater the annular resolving power. Beam width may be at different locations through the axis depending upon the shape of the antenna reflector. See also **Antenna (Communications)**.

BEAN. The fruits of many different plants and in many cases the plants themselves are called beans. Nearly all of them are members of the Leguminosae. In Europe and America, beans are principally plants of the genus *Phaseolus*, with *Phaseolus vulgaris*, the common Garden Bean, a most important species, with many varieties in cultivation. This plant is a tender annual, probably originally native in South America, and grows either as a low bush or as a twiner. Many of the varieties grown have been selected to yield a thick, rather fleshy pod with small seeds; these are string or snap beans. See Fig. 1. In some varieties chlorophyll (see **Pigmentation (Plants)**) is either entirely or largely lacking in the pods, giving the Wax or butter bean. Many other varieties are grown primarily for the dried seeds, which have a very high food value and keep exceedingly well if dried and protected from insects. Common varieties used as dry beans are Pea,

Fig. 1. Snap bean. Variety is the *Tendercrop*, a mosaic-resistant, heavy-yielding snap bean with tender, round, green pods and a wide range of adaptability. (*USDA photo*.)

Yellow Eye, and Red Kidney beans. Shell beans are those in which the nearly mature but green seed is eaten. See **Leguminosae**.

Related to the Garden Bean is *Phaseolus multiflorus*, the Scarlet Runner Bean, which is often grown as an ornamental plant because of its showy scarlet flowers. Another species, widely grown in warmer climates, is *Phaseolus lunatus*, the Lima Bean, another plant from South America. The large flat pods of this plant contain a few large flat seeds. Varieties have been developed which can successfully mature in regions having a short growing season.

In Europe a common bean is the Broad Bean, also called Windsor or Horse Bean, *Vicia faba*. Its seeds are rich in nitrogenous compounds and rather hard to digest. These seeds are extensively used for horse food, as well as for human consumption.

In the Orient, the bean crop is almost entirely *Glycine max*, the Soy Bean. The plant is an erect bushy annual with trifoliate leaves and bears fruit (pods) in great abundance. Tremendous quantities are grown in the Orient, where large populations depend upon it as the major source of protein. The plant has been introduced into the United States, where it is extensively cultivated for several reasons. One is the fact that it will grow well on poor soils and, being a legume, will build up the fertility of the soil, because of its associated nitrogen-fixing bacteria. It is also an important forage crop. The seeds are rich in oil and have received much attention from chemists, with the result that large quantities are now used in the preparation of enamels, linoleum, inks, paints, soaps, etc. This oil is used in larger quantities than any other oil for the production of vegetable shortening. The cake remaining after the oil is pressed out is used as a stock food or as a source of industrial proteins for the production of adhesives, sizings, coatings for paper, and other products.

In Africa, species of *Dolichos* are used as food.

All the plants so far treated are legumes having "bean"-like fruit. But in the Vanilla bean one deals with an entirely different plant. Vanilla beans are the fruits of a climbing orchid growing wild in Central America and Mexico. Since prehistoric times these fruits have been used to flavor chocolate. At the present time (and with some difficulty) the plant is cultivated in several tropical countries, both in America and in the Orient. Like many other orchids, the flowers are pollinated only by certain specially adapted bees, and perhaps by the hummingbirds.

Many other plants contain vanillin, or similar substances, and so are often used in the manufacture of artificial vanilla. Among these are the seeds of a tropical South American plant, Coumarouna, which yield a product coumarin, used in perfumery. The seeds from which this coumarin is obtained are called Tonka Beans.

BEAN WEEVIL *(Insecta, Coleoptera)*. The common bean weevil is a small beetle, *Mylabris obtectus*, that attacks growing beans and cowpeas in the pod. Methods of control are the same as for the pea weevil. The four-spotted bean weevil is a related species that attacks beans and peas both in the field and in storage.

BEARING. The horizontal direction of an object or point, usually measured clockwise from a reference line or direction through 360°.

A bearing is often designated as true, magnetic, compass, grid, or relative as the reference direction is true, magnetic, compass, or grid north, or heading, respectively. At one time bearing was restricted to reference to the direction of a terrestrial object or point as distinguished from azimuth, which referred to the direction of a celestial body. This distinction has been blurred by usage.

BEARING ANGLE. Horizontal direction measured from 0° at the reference direction clockwise or counterclockwise through 90° or 180°. Bearing angle is labeled with the reference direction as a prefix and the direction of measurement from the reference direction as a suffix. Thus, bearing angle N 37°W is 37° west of north, or bearing 323°.

BEARING MODULUS. The performance of a bearing may be measured in terms of a quasi-dimensionless function Zn/p, where Z is the absolute viscosity of the lubricant in centipoises, n is the journal speed in rpm, and p is the unit pressure on the bearing in pounds per square inch of projected area.

BEARING (Navigation). In both air and sea navigation, the term *bearing* is used as an indication of direction. Bearing is the angle, measured at the observer, or some specified point, between two lines in the plane of the horizon. See Fig. 1. Careful distinction must be made between the meaning of the term bearing when used alone and the same term when qualified, e.g., relative bearing, compass bearing, etc.

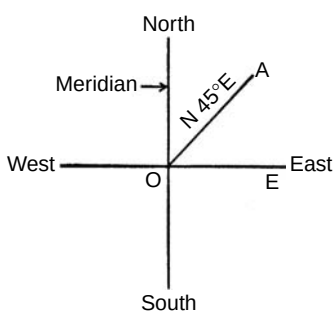

Fig. 1. Example of navigational bearing.

The bearing of a given point from the observer is simply the true direction of that point, expressed in the conventional manner for expressing direction, i.e., to the right, through 360°, and in three digits.

If the compass is used for finding the bearing of a point from a ship, the value obtained will be the compass bearing, and the compass corrections must be applied to obtain true bearing. Methods for obtaining bearings by using the pelorus are explained in the article on that instrument. See **Pelorus (or Dumb Compass)**.

Frequently, it is easier to use a ship's keel as a reference line, rather than north, for determining bearing. In this case, relative bearing is obtained. This is defined as the angle between the keel of the ship and a line in the plane of the horizon to the object. This angle is measured from the forward end of the keel, to the right through 360°, and expressed in three digits. To find the bearing of the object when the relative bearing is known, the heading must be added to the relative bearing. For example, a ship is heading 326° and the relative bearing of a buoy is 124°. The bearing of the buoy is $326^\circ + 124^\circ = 450^\circ$, or 090°, and the buoy is due east of the

ship. Radio bearings, taken with a radio direction-finder, are always given as relative bearings from the ship.

Lookouts on ships, gunners on planes, and other observers of this general type, may not have a pelorus available to determine bearings of a sighted object. Various approximate methods are in use for expressing relative bearings, depending upon the particular service. Lookouts on ships at sea frequently report relative bearings in terms of compass points. For example: an object sighted one point (11°.25) to the right of the bow would be reported as "one point off the starboard bow." An object with relative bearing 315° would be reported as "broad on the port bow," etc. In the air-services, clock numbers are sometimes used for reporting relative bearings, e.g., an object with relative bearing about 300° would be reported as "at ten o'clock." Complete descriptions of the various approximate methods used in the various services may be found in manuals of seamanship, regulations of the U.S. Air Force, etc.

In surveying, bearing is usually expressed in terms of the acute angle measured either from north or south to the east or west. For example: a bearing of 45° would be expressed as N 45°E (north 45° east); a bearing of 290° as N 70°W, etc. See Fig. 1.

The latitude of a line is its orthographic projection on the meridian; the departure is its orthographic projection on a line perpendicular to the meridian:

$$\text{latitude} = \text{length} \times \text{cosine of bearing}$$

$$\text{departure} = \text{length} \times \text{sine of bearing}$$

Latitudes are positive for north bearings and negative for south bearings. Departures are positive for east bearings and negative for west bearings. In a theoretically closed traverse the algebraic sum of both the latitudes and the departures must be zero.

The bearing of any line such as OA referred to a meridian through O is a forward bearing; if referred to a meridian through A it is a back bearing or reverse bearing. Forward and back bearings differ by 180°.

See also **Compass (Navigation)**; and **Navigation**.

BEARS *(Mammalia, Carnivora).* The general organization of Ursines may be outlined about as follows:

Brown Bears (*Ursus*)
Spectacled Bear (*Tremarctos*)
Sun-Bear (*Helarctos*)
Moon Bears (*Selenarctos*)
American Black Bear (*Euractos*)
Sloth-Bears (*Melursus*)
Polar Bears (*Thalarctos*)

Bears are found in every continent except Australia, although Africa and South America have only limited species. The term *bear* is sometimes applied to the koala (*Marsupialia*) in a superficial, erroneous fashion. The Ursines are quite closely related with the Canines. Some authorities have observed that the Ursines are huge Canines without tails. Generally, bears prefer mountainous regions and are found in the Alps, Pyrenees, Carpathians, Caucasus, the mountains and woodlands of North America, ranging from Mexico northward to the Arctic, the Andes in South America, and the hilly and mountainous areas of North Africa and southeast Asia. The Polar Bear inhabits the Arctic regions as indicated by the name. The Sloth-Bear is found in India. Bears are noted for their ability to adapt to specific regions and climes; thus, among a comparatively limited number of species (about a half-dozen), much variety is demonstrated. For example, a given species may hibernate in one region and remain active all winter in another region.

Brown Bears are often referred to by other names, reflecting the numerous variations among a given species that have arisen from years of adaptation to specific regions. The Alaskan Brown Bear, also called "Big Brownie" or the Kodiak Bear is the largest of the living bears, weighing up to 1500 or more pounds (680 kilograms). This animal also is the largest of the land carnivores. When standing erect, the height may exceed 9 feet (2.7 meters). The largest specimens are found on the islands off the coast of Alaska and notably Kodiak Island. The animal feeds extensively on salmon, captured when the fish enter the rivers for spawning. The color may range from nearly black on the dark side to nearly a blond coloration on the light side. Usually, the bear is a light brown. The Alaskan Brown Bear prefers deep underbrush. The seasonal diet of fish is augmented throughout the rest of the year with various fresh greens and even seaweed obtained along the shore. The animal also seeks out the burrows of mice and ground

Fig. 1. Brown bear. (*A.M. Winchester.*)

squirrels. When berries are in season, the bear relishes a number of wild berries, including cloudberries and crowberries, as well as the berries of the mountain ash. Some authorities state that just before hibernation, the bear consumes large quantities of cranberries, which serve as a purgative. Hibernation commences in late October or early November when dens are dug in dry hillsides. The cubs, usually twins — occasionally triplets — are born during the cold months. Appetites are high in the early spring and at that time, the bear has been known to attack horses and cattle. Over recent years, the Alaskan Brown Bear has been overhunted, both for sport and by natives who eat the meat and utilize the hides. See Fig. 1.

Also included among the Brown Bears is the Grizzly Bear (*U. horribilis*), closely related to the Alaskan Brown Bear. The weight of an adult Grizzly Bear will range from 800 to 1400 pounds (363 to 635 kilograms). The animal is found in the wilderness of North America. So-called grizzlies are also found in eastern Asia. Other Brown Bears include the Tibetan Brown Bear (*U. pruinosus*); and the Isabelline Bear, an inhabitant of the Himalayas and known for its beautiful cream-colored coat. Other large races occur in Eastern Siberia and Kamchatka, as well as in Syria.

General characteristics of the Brown Bears would include: by nature, peaceful and not inclined to molest humans unless provoked; more dangerous than the big cats, however, if approached unexpectedly or provoked; possessing a rather clumsy gait, a lumbering type of walk; very swift and powerful when necessary; large eaters, of both vegetable matter and animal flesh, but with a preference for sweets, such as honey, and a relish for fish; quite immune to insects; accumulating large quantities of fat in their bodies just prior to hibernation; the young are small, seldom larger than a small rabbit.

The American Black Bear (*Euarclos*) is smaller than the Brown Bear, but is not necessarily black. There are a number of brown Black Bears, giving rise to various names including the Cinnamon Bear, the Glacier Bear, and the Kermode Bear. The American Black Bear, weighing from 200 to 500 pounds (91 to 227 kilograms), is the common bear of North America and is distributed rather widely throughout Canada, the United States, and northern Mexico. The appearance is distinguished from most other bears by the lack of a hump between the shoulders. In earlier years, it appeared that the American Black Bear might be threatened, but since the species has penetrated further into the wilderness, the trend reversed and now the population appears to be increasing slowly. This bear sleeps for long periods during winter, but authorities generally do not designate this as true hibernation. The animal is omnivorous, eating a variety of materials ranging from pine cones to wasp's nests. In captivity, the animal is dangerous to feed because it assumes that when the food runs out, the giver is holding back. Usually three cubs, about the size of a rat, are born annually. An Asiatic black bear is shown in Fig. 2.

The Spectacled Bear (*Tremarctos*) inhabits the mountainous region of the Andes in South America. Of two species, one lives in Bolivia and another in Chile. The name is derived from yellow rings around the eyes, which contrast with the shaggy, black body. See Fig. 3.

The Sun-Bear (*Helarctos*) has not been fully studied. It attains a length of some $4\frac{1}{2}$ feet (1.4 meters) and has a pronounced short, wide, and flat head. They are known as excellent tree climbers. See Fig. 4.

Fig. 2. Asiatic black bear. (*Salenarctos thibetanus*.)

Fig. 3. Spectacled bear. (*Tremarctos ornatus*.)

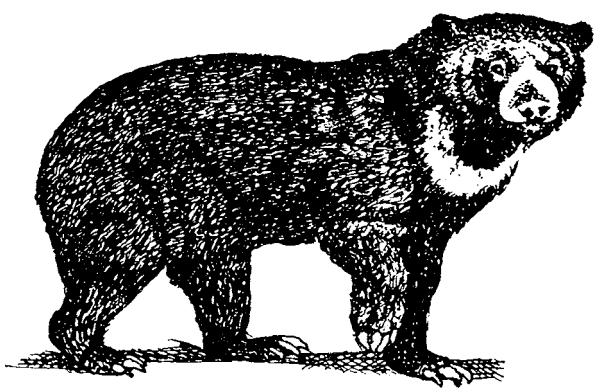

Fig. 4. Malayan sun bear. (*Helarctos malayanus*.)

The Moon Bear (*Selanarctos*) is found in south-central Asia, in Japan, Taiwan, as far west as Iran, and as far south as northern Pakistan and India. The animal is characterized by a V-mark on its chest and a white upper lip, both features contrasting well with the animal's black body. More than most bears, the Moon Bear is a vegetarian. However, it retains a relish for honey and sweet-tasting insects, characteristic of most bears. This bear is essentially oblivious to humans and it is reported that it can be readily approached without harm.

The Sloth-Bear (*Melursus*) is an inhabitant of India. See Fig. 5. The animal is characterized by a rather long, anteater-type snout, huge claws, and small teeth. Like the anteater, this bear is quite insectivorous. The

Fig. 5. Sloth bear. (*Melursus ursinus*.)

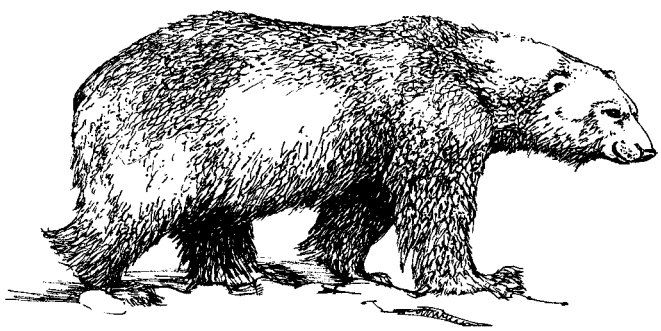

Fig. 6. Polar bear. (*Thalarctos maritimus*.)

animal has a naked face of gray color, with long, shaggy black fur over the body. The chest carries a white marking.

The Polar Bear (*Thalarctos*), sometimes referred to as the Water Bear or Ice Bear, has a thick, white coat, including fur on the soles of the feet, and, while possessing the characteristic profile of other bears, is somewhat distinguished by a longer, more slender neck, a more pointed head, and a large, high rump. See Fig. 6. The animal may attain a weight of 1000 pounds (454 kilograms) or more. The Polar Bear is an excellent swimmer, capable of covering wide expanses of water. It is noteworthy that during the summer season, the animal usually lives on ice floes, infrequently going on land. A major dietary item is the seal. The animal is known to swim for considerable distances underwater in effecting its strategy for surprising a seal. The young are born in the spring, usually in a natural cave that has been sought out by the female, or in a cave comprised of a rock and hollowed-out snow and ice. The males, with the exception of older animals, also hibernate throughout the winter. Found throughout the Arctic region, these bears always have been important to Eskimos for food, hides, and bones, from which implements are made. For references, see **Mammalia**.

BEAT. A series of alternate maxima and minima in vibration amplitude, produced by the interference of two wave trains of different frequency. A familiar example arises in the case of musical sounds. If two musical pipes or strings of slightly different pitch are sounded together, the result is a more or less distinct throbbing, often disagreeable to the ear. The beat frequency is the difference of the two wave frequencies. Thus, if the two tones are middle-c (256) and c-sharp (271.2), there will be 15.2

beats per second. If the two tones are ultrasonic, but have a frequency difference within the audible range, the beats themselves may produce an audible "beat tone" or "beat note." A similar effect results from the simultaneous reception of two radio wave trains that are nearly, but not quite, synchronized. See Fig. 1.

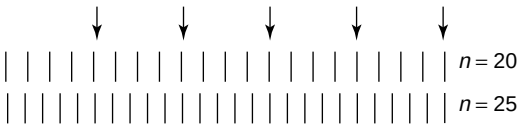

Fig. 1. Five coincidences in unit time between wave trains of frequencies 20 and 25.

When two sinusoidal signals of different frequencies are applied to a circuit whose output signal amplitude is proportional to the square or higher power of the input signal amplitude, frequency components will be produced in the output which are not all present in the input signal. Among the frequencies present will be one equal to the sum of the two original frequencies and one that has a frequency equal to the difference of the two applied frequencies. This difference frequency is known as the beat frequency. There are numerous applications of this effect, but two of the major ones in the communications fields are in the reception of continuous wave signals and in frequency shifting as in the superheterodyne receiver. Since continuous wave signals have no audio modulation superimposed on them, they cannot be made audible by ordinary detection methods. However, if the incoming signal is beat with a local signal, differing by an audible amount, the result is an audible beat frequency. Frequency shifting by use of beat frequencies is applied in the superheterodyne, in carrier telephony, frequency modulation, and numerous other circuits. In most of these applications use is made of the fact that if one of the signals is modulated, the beat frequency signal will have the same modulation.

The process wherein additional frequency components are created by passage of two signals through a nonlinear device as described above is sometimes spoken of as mixing.

BEAT NOTE. The wave of difference frequency created when two sinusoidal waves of different frequencies are supplied to a nonlinear device.

BEAUFORT WIND SCALE. A system of estimating and reporting wind speeds using a numerical scale ranging from 0 (calm) to 12 (hurricane). It was invented in the early nineteenth century by Admiral Beaufort of the British Navy and was originally based on the effects of various wind speeds on the amount of canvas that a full-rigged frigate of the period could carry. It has since been modified and modernized and in its present form for international meteorological use it equates 1) Beaufort force (or Beaufort number), 2) wind speed, 3) descriptive term, and 4) visible effects upon land objects or sea surface. One land adaptation is the NRM wind scale. See also **Winds and Air Movement**.

BEAVER *(Mammalia, Rodentia).* An aquatic species with a body length up to 100 centimeters (39 inches), a tail length up to 30 centimeters (12 inches), and a body weight up to 30 kilograms (66 pounds). The beaver has a heavy build and is one of the largest rodents. The body comes large as one looks at it from front to back. The hind feet have web membranes between the toes. The small forefeet are particularly good gripping tools. The feet all have five digits, all with strong nails. The second toes on the hind feet carry a weak double claw that is used for cleaning the fur. Beavers have strong bristly hair, and their woolly hair is curled thickly. The tail is flat, 12 to 15 centimeters (5 to 6 inches) wide, and shaped like a ladle, with scaly, leather-like skin; the beaver uses it as a rudder. On land the beaver looks awkward, but in the water it is an outstanding swimmer and diver. These animals are exclusively herbivorous. In summer, they eat the juicy shrubs found on riverbanks, bulrushes, buds from softwood trees (especially poplars, aspens, and willows), as well as root pieces from water lilies. In winter, beavers will eat bark from shrubs and from trees they cut down. See Fig. 1.

There are several subspecies, including the Scandinavian Beaver (*Castor fiber fiber*); the Elbe Beaver (*Castor fiber albicus*); the Rhone Beaver (*Castor fiber galliae*); the Polish or Byelorussian Beaver (*Castor fiber vistulanus*); the Ural Beaver (*Castor fiber pohlei*); the Mongolian Beaver (*Castor fiber birulai*); and, from North America, the Canadian Beaver

Fig. 1. Beaver. (*A.M. Winchester*.)

(*Castor fiber canadensis*); the Michigan Beaver (*Castor fiber michiganensis*); the Newfoundland Beaver (*Castor fiber caecator*); the Rio Grande Beaver (*Castor fiber frondator*); the Golden-Bellied Beaver (*Castor fiber subauratus*).

Beavers live much of their life in water; they settle along the banks of streams, rivers, and lakes in the thick underbrush of lowland woods. When the beaver lives near a large river full of rushing water, or when it lives near a river which is too wide to be dammed up, it builds a simple house in the riverbank, with at least two entrances, and sometimes four or five, all of which are underwater. The Elbe beaver often makes these simple living quarters in riverbanks. The entranceway rises on a diagonal from just below the water's surface to immediately below the surface of the ground. There the animals build a room which is some 4 feet (1.2 meters) wide and 15.7–19.7 inches (40–50 centimeters) high, and very carefully smoothed out on the inside. When the surface of the water rises, the floor of the room must also be raised; in order to accomplish this, the beaver gnaws or scrapes dirt from the ceiling, and this dirt then falls on the floor. Usually the ceiling is so strong that several people can stand on it together without mishap. However, if the beaver is forced to make its house somewhat higher, it strengthens the ceiling with mounds of twigs, which it lays outside over the ceiling. These can become regular mountains of twigs. As the water level rises, the height of the mound must be increased, and finally it becomes an island in the water.

If a river or lake should dry up, the entrances to the beaver mound are above the water. Beavers build dams to keep the water at a constant level and, even more, to create artificial reservoirs where they feel secure and to which they can easily transport their food. The animals build their dams by placing tree trunks and branches, which they have cut down and prepared, in the ground, perpendicular to the riverbed, and by fastening and anchoring these uprights with stones, mud, reeds, and whatever else might be at hand. The beavers will often make a support out of a tree that has fallen across or floated down the river, so they can expand their construction. The more the water behind the dam rises, filling the creek or riverbed, the higher the beavers must make their dam, extending it on the sides to the higher riverbanks. The longest dam in the Voronezh region in the former U.S.S.R. is near Marinika; it is 394 feet (120 meters) long, 3.3 feet (1 meter) high, and from 23.6 to 39 inches (60 to 100 centimeters) wide. The dams across the mountain streams at the foot of the Rocky Mountains in North America are up to 10 feet (3 meters) high. The largest beaver dam of all is that on the Jefferson River, near Three Forks, Montana; one can follow it for 2297 feet (700 meters). This dam has been maintained by successive beaver generations for decades, perhaps even centuries, as long as enough food for these animals can be found in the area. There is a dam in Colorado that has been there for 70 years; trees and bushes finally grew on top of it, and the dam itself keeps getting wider and stronger. It takes a family of beavers about a week to build a dam that is 33 feet (10 meters) long. When the river has a strong current, the beavers build several auxiliary dams facing the current so that the main dam will not

be destroyed. If the water breaks through the dam at a single point, the beavers will rapidly repair the leak the next night. Our expression for feverish activity, "to work like a beaver," comes about as a result of the industriousness of these animals. The dams differ according to area and subspecies. The dams in the flat swamplands of Mississippi often reach gigantic dimensions, several hundred meters in length, and the area that has been inundated provides the beaver with a large habitat.

Humans have always praised the beaver because it can fell a tree so that the crown always lies toward the water and because these animals calculate the fall of the tree so exactly that no beaver is killed in the process. In addition, beavers seem to be able to judge the direction of the tree's fall so that the crown of the tree is not caught in nearby trees and so that the tree itself does not fall in an area where it would be of no use to the beaver.

Beavers like to gnaw through tree trunks between 3.1 to 8 inches (8 to 20 centimeters) in diameter; they like aspens, willows, and poplars, and are somewhat less enthusiastic about birch and wild cherry trees. They almost completely ignore the coniferous trees, and thereby avoid harming our most important timber and hardwood trees. Two beavers often work together on a thick tree; usually one animal cuts while the other looks around. Of course, beavers prefer trees that grow close to the water. They drag thin tree trunks as well as branches they have cut from larger trees to the water by the shortest possible route. They do not cut down trees that are more than 650 feet (200 meters) from the water. After they have cut down everything within the circumference of their colony, they like to move to a new area.

Beavers place several of their harvested branches in the water around their mounds, making sure that the gnawed end is stuck firmly into the mud of the riverbed so the branch does not float away. These branches are provisions, particularly for the winter months, because in the summer these animals can also eat water plants, berries, swampwood roots, and, where possible, cultivated fruit. However, their main diet consists of fresh green bark and softwood. Hard nutrition of this type is in keeping with the strength of these animals' teeth. A single beaver exerts a chewing force of 176 pounds (80 kilograms) with its incisors; humans exert a force of only 88 pounds (40 kilograms). In addition, the beaver weighs 40–44 pounds (18–20 kilograms), 66 pounds (30 kilograms) at the very highest.

Beavers do not hibernate, although they become much less active during the cold season. One may not see them for as long as a week. When it is 59 °F (15 °C) outside, the air in the beaver's house remains at about the freezing point. As soon as the river freezes, the beaver swims under the ice to its storage supply of branches. Often they do not even have to make air holes in the ice, because the ice in rivers and lakes begins to freeze first at the edges, near the banks. Then, in the course of the winter, the water level sinks to some extent, especially in rivers. Thus the ice in the middle of the river sinks while the ice near the banks of the river is held up by the ground and the roots of trees, leaving safe and secure air pockets for the beaver.

Beavers are sexually mature after 3 to 4 years. Copulation takes place in the water between January and March. The male swims under the female, with his stomach facing upward. According to most observations, it appears that beavers form permanent pair bonds, although when the young are born in the beaver mound (after a gestation of 105–107 days), the male and the young from the previous year, must move out of the structure for some time. Young beavers have hair on their bodies and are able to see at birth. Their eyes are half-closed at birth and covered with a thick fluid. The incisors are already visible. Young beavers nurse for almost 2 months; they grow noticeably during this time. The beaver mother often places her tail under her stomach and lifts one leg so that the young can sit on her warm tail for support while they nurse.

Young beavers are also able to swim and dive very early. If they remain in the water, the mother often transports them back to the house forcibly. Bolau, director of the old Hamburg zoo (which is no longer in existence), once wrote that when she travels on land, the beaver mother carries her young in her outstretched forelegs and walks on her two hind legs. This description was hard to believe, but some 50 years later, this unbelievable method of carrying the young was observed and photographed in the Zurich zoo. The mother can also carry her young about by having them sit on her tail.

Usually three generations of beavers live together in one mound. The parents always drive the oldest offspring out of the den, by biting them, in order to make room for the new litter. Beavers can live to be 10 to 15 years old.

The fur of the beaver has been among the most valuable on the market and has been the chief reason for a slaughter that threatened to destroy the species. With rigid protection they have become numerous in some parts of North America during the present century so the threatened extinction has apparently been averted.

Other rodents are covered under **Rodentia**; and **Squirrels and Other Sciuromorphs**.

BECKE TEST. A microscope of moderate or high magnification is used to compare the indices of refraction of two contiguous minerals (or of a mineral and a mounting medium or immersion liquid), in a thin section or other mount. When the two substances differ substantially in refractive index, they are separated by a bright line, called the *Becke line*. The line moves toward the less refractive of two materials when the tube of the microscope is lowered.

BECKMANN, ERNST (1853–1923). Beckmann was a German chemist who discovered in 1886 the arrangement of oximes of ketones into acid amides or anilides, named the Beckmann molecular transformation. He was the inventor of two pieces of apparatus used in determining freezing and boiling points of solutions. The Beckmann thermometer is used for determining molecular weights in solutions.

See also **Beckmann Method**.

J. M. I.

BECKMANN METHOD. A method of measuring elevation of the boiling point or depression of the freezing point of a solution. It may be used to measure concentration if the nature of the solute is known, or the molecular weight of the solute if the volume concentration is known. See also **Analysis (Chemical)**; and **Freezing-Point Depression**.

BECQUEREL, ANTOINE HENRI (1852–1908). Becquerel, a Frenchman, represented the third generation in his family to become a physicist. He was trained as an engineer beginning his research career at the Ecole Polytechnique in 1875. His early research was work was concerned with the plane polarization of light, with the phenomenon of phosphorescence and with the absorption of light by crystals (his doctorate thesis). He also worked on the subject of terrestrial magnetism.

Becquerel invented a phosphoroscope to study phosphorescence. He is most famous for his discovery of natural radioactivity, a property of uranium, in 1896. His discovery lead eventually to the atomic and nuclear age and the research work of Marie and Pierre Curie. Becquerel shared the Nobel Prize in Physics in 1903 with Marie and Pierre Curie for "his discovery of spontaneous radioactivity".

See also **Becquerel Effect**.

J. M. I.

BECQUEREL EFFECT. A photographic effect discovered by E. Becquerel (1895). Experimenting with the daguerreotype process, Becquerel found that a plate will produce a direct (positive) image if exposed first to diffuse daylight. See also **Photography and Imagery**.

BEDBUG *(Insecta, Hemiptera).* A wingless, blood-sucking bug which hides during daylight in the crevices of beds and other furniture and about the woodwork of houses and seeks its victims at night. It has been found also about chicken roosts.

Severe infestations are usually handled by fumigation of the entire building.

This species, *Cimex lectularius*, gives the name bedbug to the family *Cimicidae*, which also contains a few species that attack bats and birds.

Still another member of this order, the large bedbug, is sometimes found in beds. It is almost an inch (2.5 centimeters) long and is capable of

inflicting a painful wound. This species is one of the assassin bugs (family *Reduviidae*).

BEDDING. A term used by geologists to designate the natural layering or stratification usually characteristic of sediments and sedimentary rocks. Bedding is the result of the unequal rates of settling of particles of different sizes and specific gravities. In the case of very fine-grained sediments, or shales, the bedding may be shown by color bands. The thickness of a bed or stratum may vary from several feet (meters) to a fraction of an inch (centimeter). Extremely thin beds are called laminae.

BEDROCK. The solid rock of the lithosphere, which may be directly exposed or covered by loose unconsolidated materials such as sand, clay and soil.

BEECH TREES. Members of the family *Fagaceae* (beech family), these trees are of two principal genera: *Fagus*, large, hardy, deciduous trees; and *Nothofagus*, deciduous or evergreen shrubs and trees occurring in the southern hemisphere and sometimes collectively referred to as southern beeches. Important species of the beech family include:

American beech	*Fagus grandifolia*
Antarctic beech	*Nothofagus antarctica*
Black beech	*N. solandri*
Common or European beech	*F. sylvatica*
Copper beech	*F. s. cuprea*
Dawyck or upright beech	*F. s. Dawyck*
Fern-leafed beech	*F. s. heterophylla*
Mountain beech	*N. cliffortioides*
New Zealand black beech	*N. solandri*
Purple beech	*F. s. purpurea*
Red beech	*N. fusca*
Weeping beech	*F. s. purpurea pendula*

The American beech is found in the eastern part of the United States, from Maine to the Gulf Coast and throughout the Midwestern states. The tree is tall, stately, and large. The height averages 60–75 feet (18–23 meters), with a trunk from 2 to 3 feet (0.6 to 0.9 meter) in diameter. The leaf is 3 to 5 inches (7.6 to 12.7 centimeters) long, dark green, sharply toothed, ovate, and deeply veined. The bud is encased in thick bronze-colored scales. The bud is slender, pointed, and about 3/4 inch (2 centimeters) in length. The nut or fruit is dark brown, smooth and with a rough cap that covers nearly half of it. The kernel is bitter, but squirrels seem to like it. The flower is long, 2 to $2\frac{1}{2}$ inches (5 to 6 centimeters), light green, has a wormlike shape, and hangs in clusters from the branch of the tree. Beech wood is generally heavy, hard, tough, and of closed-grained structure. The light color is similar to that of maple. The wood has been used as veneer, for tool handles, shoe lasts, cooperage, and pulpwood. The wood is particularly suited to the production of small items, many of which now have been replaced by plastics. The moisture content of green beech wood is 54%, with a weight of about 54 pounds per cubic foot (865 kilograms per cubic meter). After air-drying to 12% moisture content, the weight is 45 pounds per cubic foot (720 kilograms per cubic meter) and 1000 board feet (2.36 cubic meter) of nominal sizes weigh 3750 pounds (1701 kilograms). The crushing strength with compression applied parallel to the grain for green wood is 2200 psi (15.2 MPa); for dried wood, 4730 psi (32.6 MPa). The tensile strength with tension applied perpendicular to the grain for green wood is 720 psi (5 MPa); for dried wood, 1010 psi (7 MPa). The record American beech, as selected by American Forest in 1994, is located in Harwood, MD. Circumference at 41/2 feet (1.4 meters) above ground level is 279 inches (709 centimeters); height is 115 feet (35.1 meters); spread is 138 feet (42.1 meters).

The European beech (F. sylvatica) is not as heavy as the American species, but it is used in much the same way. The wood is a red-brown color. The tree is popular as a hedge. Although not typical, the possibilities of the tree as an effective hedge is exemplified by the huge hedge at Meikelour (Scottish Highlands), which is 95 feet (28.5 meters) high and 580 yards (530 meters) long. The European beech has done particularly well in Normandy, where specimens over a few hundred years old are found.

It is interesting to note that the beech is notable among the broad-leaved trees for its establishment in both the northern and southern hemispheres. In New Zealand, the *Nothofagus solandri* is also known as red beech, black beech, or tawhai beech. The tree is slender and has rising branches. It may attain a height of 80 feet (24 meters). The wood is strong, durable, and heavy, weighing up to 44 pounds per cubic foot (704 kilograms per cubic meter). The antarctic beech, also known as the rauli tree, is found in Chile and replaces some of the functions of oak wood in South America. It can attain a height of 100 feet (30 meters) or more.

See also **Tree**.

BEEF CATTLE. See **Bovines**; and **Cattle**.

BEE FLY *(Insecta, Diptera)*. Flies, small to medium-sized, often bee-like, whose habit of visiting flowers for pollen and nectar is like that of the bees. The larvae are parasitic, some on bees. They make up the family *Bombyliidae*.

BEE LOUSE *(Insecta, Diptera)*. A minute, wingless, parasitic fly found attached to the queen and drones in honeybee colonies. The few known species constitute the family *Braulidae*, containing the genus *Braula*.

BEE-MOTH *(Insecta, Lepidoptera)*. A moth whose larva eats the wax and debris in old honeycombs, spinning a silken tunnel as it goes. These insects are found chiefly in weak colonies of bees and in stored combs. They may attack beeswax products, such as comb foundation in the supplies of the apiarist, but they cannot develop on a diet of pure wax; the organic waste in old brood combs provides the necessary nitrogenous material and furnishes a favorable breeding place. The best-known form is *Galleria mellonella*.

In well-kept apiaries the bee-moth is rarely a serious pest. The maintenance of strong colonies of bees prevents its entrance and the protection of stored supplies against the entry of the adult moths safeguards them against damage. Fumigation of supplies is sometimes necessary.

BEER AND OTHER MALT BEVERAGES. Beer is an effervescent beverage resulting from the thorough alcoholic fermentation of a hopped solution, in potable water, of the extractive substances principally of barley malt, together with, if desired, other prepared cereals (corn [maize], rice, etc.) or their natural equivalents. A typical American beer contains 92.1% water and 3.4 to 3.6% alcohol by weight (4.3 to 4.5% alcohol by volume), the remaining being largely made up of carbohydrates. See Table 1. *Nonalcoholic* beer is growing in popularity in a number of countries, including the United States, and is described later in this article.

TABLE 1. ANALYTICAL PROFILE OF LAGER BEER (per 100 grams)

Water	92.1 g
Food energy	42 cal
Protein	0.3 g
Fat	0
Carbohydrates	3.8 g
Calcium	30 mg
Phosphorus	Trace
Iron	7 mg
Sodium	25 mg
Potassium	0
Vitamin A	0.002 mg
Thiamine	0.03 mg
Riboflavin	0.6 mg
Vitamin C (ascorbic acid)	—

Beers and Ales. For convenience, malt beverages can be considered in two broad classifications: (1) ales and (2) beers. There are two major processing differences. Ales are fermented at a higher temperature with a yeast that rises to the top of the fermentation vessel, whereas beers are fermented at lower temperatures with a yeast that settles to the bottom. There are subcategories of both classes of beverages.

The principal ale-type beverages are *ale*, *porter*, and *stout*. These usually contain a greater percentage of alcohol than beers. As compared with regular ale, porter tends to produce a richer, heavier foam and has a sweeter taste, notably with the taste and aroma of hops less pronounced. The dark color of porter results from the use of some dark or black malt in its preparation. As compared with regular ale, stout is more heavily bodied

and possesses a pronounced hops flavor. The color of stout is dark; the taste is sweet, with an accompanying strong malt flavor.

The term *beer* generally connotes a lager-type beer, which is described in the first paragraph of this article. The term *light beer* became popular in the United States in the late 1970s and connotes a beer with a reduced carbohydrate content, in keeping with the growing awareness of food calorie intake by consumers. *Bock beer* is traditionally available in early spring and has a darker color, resulting from the use of carmelized or highly roasted malt. The alcoholic content is somewhat higher and is more full-bodied than regular lager beers.

Chronology of Brewing. Throughout its history of many centuries, the brewing of ales and beers traditionally has been a highly localized undertaking. Thus, until the early part of the twentieth century, brewing was a geographically decentralized industry. Thus, towns and cities and regions of countries developed preferences for local beverages, giving rise to types and designations of beers, such as Pilsener, Wiener, and Mueenchner in Germany, and the previously mentioned subcategories of ale, such as porter and stout, as developed in the British Isles and Ireland. Most of these product differences, some marked and others subtle, were developed before the growth of the brewing industry of North America. For the first few centuries of beverage production in North America, brewers received their skills from Europe, following the established recipes and nomenclature. North American brewers have adapted new knowledge of organic chemistry and advanced chemical engineering to the point where American brewers are highly respected throughout the world.

The general nature of brewing in the United States changed considerably after the repeal of the 18th Amendment to the Constitution (prohibition of alcoholic beverages) by approval of the 21st Amendment. Prior to the "dry" period, which commenced in 1920, brewing was highly localized, there being about 1200 breweries in the country in 1920[1] Much of the beer sold was dark, non-pasteurized, draught beer. When many breweries reopened in 1932 (alcohol again became legal in 1933), the trend toward fewer, more centralized operations and the bottling and pasteurizing of lighter beer and ale commenced. It became evident that the distribution of non-pasteurized keg beer no longer fitted consumer patterns as well as bottled and then, later, canned products. Because of economies gained by large-scale processing and improvements in transportation, the number of brewing establishments has continued to decrease. In the mid-1950s, there were about 300 breweries in the United States. As of the late 1970s, this figure was reduced to well under 100 establishments. Thus, since the mid-1950s, only one-third the number of breweries produced over twice the volume of beer.

Brewing Processes. The essential step in the brewing of beers and ales involves adding yeast to a water extract of germinated barley (malt wort) that has been flavored with hops. Brewing yeasts, which are specially selected strains of *Saccharomyces cerevisiae* and *S. carlsbergensis*, ferment the principal sugars in the wort (maltose and glucose) to yield beer or ale. The fermentation of malt wort comes only as a climax of a whole series of operations, and the taste, aroma, and appearance of the beverage depend to a large extent on the stages leading to the fermentation — namely, the preparation of the malt wort. (See **Malt**.) Two main types of brewing yeasts are recognized. Some strains tend to rise to the top of the wort during fermentation and so are termed *top-fermentation yeasts*. These yeasts are used for brewing ales, porters, and stouts, as encountered in Ireland and the United Kingdom and to a lesser extent in Europe and the Americas. Other strains of yeast settle to the bottom of the wort and thus are called *bottom-fermentation* yeasts. Overall, the bulk of the world's beer is produced by the latter yeasts, which yield lager beers of various types as preferred in much of Europe and in the Americas. As pointed out earlier, the fermentation temperatures used with the two kinds of yeast are different. A generalized flow sheet of a brewing process is given in Fig. 1.

The ethanol produced by alcoholic fermentation is responsible for much of the desired potency in an alcoholic beverage, but many of the more subtle qualities of taste and aroma are caused by qualitatively minor products of the yeast fermentation, particularly higher alcohols and esters of these alcohols. When chromatographic techniques were introduced several years ago, it became possible to assess these organoleptically important volatile products in alcoholic beverages.

Substantial quantities of grain are used in the brewing industry. For example, 30 pounds (13.6 kilograms) of barley, 10 pounds (4.5 kilograms) of corn (maize), and 5 pounds (2.5 kilograms) of rice are required to brew 1 barrel of beer of 31 gallons (117 liters). In the United States alone, over 5 billion pounds (2.3 billion kilograms) of barley, 2 billion pounds (0.9 billion kilograms) of corn (maize), and 650 million pounds (295 million kilograms) of rice are required by the brewing industry per year.

Approximately 0.25 pound (0.11 kilogram) of yeast is used to brew 1 barrel of beer. The yeast grows and reproduces during the fermentation process with the end result that approximately 1 pound (0.45 kilogram) is produced for each barrel of beer fermented. One-fourth of the yeast is used in the succeeding fermentation; three-fourths is available for use in foods and feeds from each barrel of beer. This amounts to approximately 70,000 tons (63,000 metric tons) of brewer's yeast being produced in the beer industry in the United States per year.

Cereal Cooking and Mashing. With reference to the process flowsheet, it will be noted that there are two major lines of materials flowing to the *mash tun* (vessel in which the mashing operation takes place). The first involves the handling of the barley malt. The malt is crushed in roller-type grinders. The operation is relatively gentle, so as to minimize the damage to husks, because these later serve as a filtering medium. Further, excessive crushing may cause the release of undesirable polyphenolic substances that affect flavor and stability of the final product. The crushed malt is then weighed so as to maintain the proper proportioning with cereal adjuncts. For very heavy-bodied ales, 100% malt feed can be used, but usually a somewhat lighter product is desired, and for this corn or rice may be used. Their only purpose is to furnish additional carbohydrates for later fermentation, and thus, by having this additional source of carbohydrates, the concentration of the malt flavor can be reduced. Proportioning of cereal adjuncts to malt can vary over a wide margin, depending upon the characteristic body, flavor, and aroma desired in the final product. Once a brewer has established the recipe for the final product, proportioning thereafter must be accurately controlled in order to obtain a uniformly consistent final product. The cereal adjuncts must be ground and weighed, after which they are cooked.

Thus, malt and cooked cereal adjuncts are mixed with water in the mash tun, which is equipped with an agitator. The mash tun has a perforated false bottom and a supply of warm and cold water. The enzymes that were formed during the earlier processing of the barley into malt again become active. The starch present is converted by amylase into maltose or intermediate products (dextrins). The normal conversion products are 80% maltose and 20% dextrins, plus small quantities of trisaccharides. Maltose formation is favored within a temperature range of 135° to 143.5 °F (57.2° to 62 °C) and at a pH of 5 to 5.5. The complex protein molecules are broken down by other enzymes present. Proteolytic enzyme activity is optimal at a temperature range of 118° to 122 °F (47.8° to 50 °C) and a pH of 4.3 to 5.0. Later, the temperature in the mash tun is raised to above 175 °F (79.3 °C) with hot water and steam. When mashing is complete (2 to 3 hours, depending upon the end product), the insoluble material settles to the bottom where it acts as a filtering medium. The straining device is sometimes called a *lauter tun*. The resulting solution is called *wort*. The residue of sprouting grain is screened and pressed, possibly mixed with other feed ingredients, dried, and marketed as livestock feed.

The wort proceeds to the brew kettle where it is boiled with hops. The boiling extracts taste and aroma constituents from the hops. The wort is then strained to remove the hop residues, after which it is cooled and piped to fermenting tubs or vessels. During the cooling operation, the clear wort may also be aerated. Yeast is added to the fermenting tubs to cause transformation of the fermentable sugars in the wort into alcohol and carbon dioxide, a process that requires from 4 to 7 days. The resulting product is beer. It is subjected to cooling and aging, further filtering, and pasteurizing (if bottled or canned). Kegged beer is not pasteurized and, consequently, has limited shelf life. Some brewers use carbon dioxide recovered from the fermenting operation to recarbonate the product. The latter finishing processes can be tailored to a particular brewer's product. For example, young beer (Ruh beer) may be aged for just a few days or for a month or more. Aging is sometimes referred to as *lagering*.

[1] The reduction in number of breweries in the United States was not the result of the 18th Amendment. The so-called temperance movement had commenced many years before. The maximum number of breweries occurred in 1899, when there were 1959 establishments. As the result of numerous states "going dry," the figure had been reduced to about 1200 in 1920.

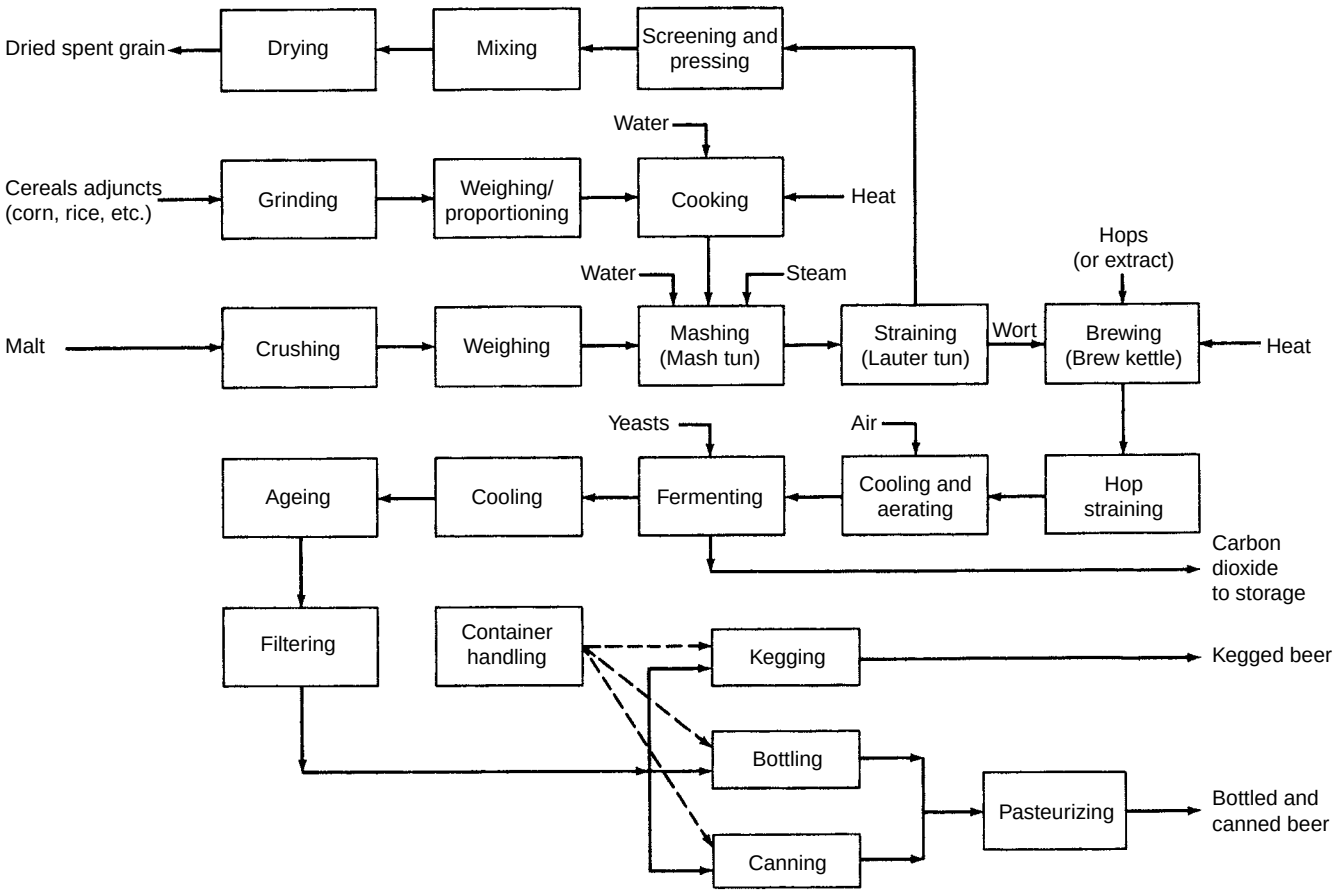

Fig. 1. Simplified flowsheet of a typical brewing process.

When beer that has not been chill-proofed is subjected to refrigeration, a haze forms in the beer. This turbidity is produced mainly by the association of proteins and polyphenols, which leads to very high molecular-weight complexes that are insoluble at a lower temperature. To avoid haze formation, it is necessary to lower the protein or the tannin content of the beer. This is the chill-proofing step of beer production, which gives a beer that will remain clear and brilliant when refrigerated. Most frequently, in beer processing, the protein content is lowered. This is achieved by an enzymatic proteolysis, using a commercial chill-proofer containing *papain*. This protease, which is in fact a crude extract from a tropical tree (*Carica papaya*), has been used widely in the brewing industry. Nominally, from 0.2 to 2 grams of enzyme preparation are added per barrel of beer. In recent years, advances have been made in chill-proofing. For example, the Laboratorie de Genie Biochimique (Toulouse, France) has reported a new form of papain for use in brewing.

Nonalcoholic Beers. To date, a beer containing absolutely *no alcohol* has not been achieved, but some brewers have achieved a beer with an alcoholic content of only 0.02% (weight). The oldest and most widely used process for removing alcohol from normally brewed beer is *vacuum distillation*. Basic to the process, however, is removal of the flavor-producing esters along with the alcohol. Sometimes a very small fraction of regular beer may be introduced to enhance flavor. Corn (maize) or cereal may be added to reintroduce traditional "beer flavor."

A *diffusion* or *reverse osmosis* method can also be used. Beer is essentially required to pass through a semipermeable membrane. After this process, the beer minus alcohol remains. While effective, the process is costly and complex.

In another method, the *fermentation process is altered*. One Swiss brewer uses a special yeast that ferments only about 1% of the sugars found in the wort. It is reported that the special yeast is difficult to control under processing conditions. Still another method is that of allowing normal fermentation to commence, but halting it early in the process, not permitting it to proceed to completion as with normal beer.

U.S. regulations define a nonalcoholic beer as one with 0.5% or less alcohol. Nonalcoholic beers have the advantage of containing approximately 55 calories (average glass) by contrast with the 150 calories for regular beer.

BEER'S LAW. If the Bouguer law is applied to a solution of fixed thickness, b cm. and concentration c, the result is log $I_0/I = abc$ which is the fundamental equation of quantitative absorptimetry. Here I/I_0 is the transmittance and the constant a, the absorptivity depends on the nature of the absorbing material, the wavelength of the incident radiation, the nature of the solvent, the temperature, and perhaps other controllable experimental conditions. When c is given in moles per liter, a is called the molar absorptivity. If other concentration units are more convenient, the numerical value of a must be changed accordingly. The product $A = abc$ is the absorbance of the sample and it equals $1/T$, the reciprocal of the transmittance. Experimental verification of Beer's law will succeed only if appropriate corrections are made or can be neglected as with the Bouguer law.

BEET *(Beta vulgaris; Chenopodiaceae).* The many varieties of beets now in cultivation are perhaps all derived from the native *Beta maritima* of southern Europe.

The most important variety is the sugar beet, which in recent years has become an important rival of the sugar cane. As a source of sugar, beets were first utilized in Germany and in France about 1800. In the United States they became important commercially only after World War I. Sugar beets are now raised commercially in several areas, California, Utah, Idaho, Oregon, and Washington; the Eastern Slope of the Rocky Mountains; Iowa and Minnesota; and in the Michigan-Ohio area. See Fig. 1.

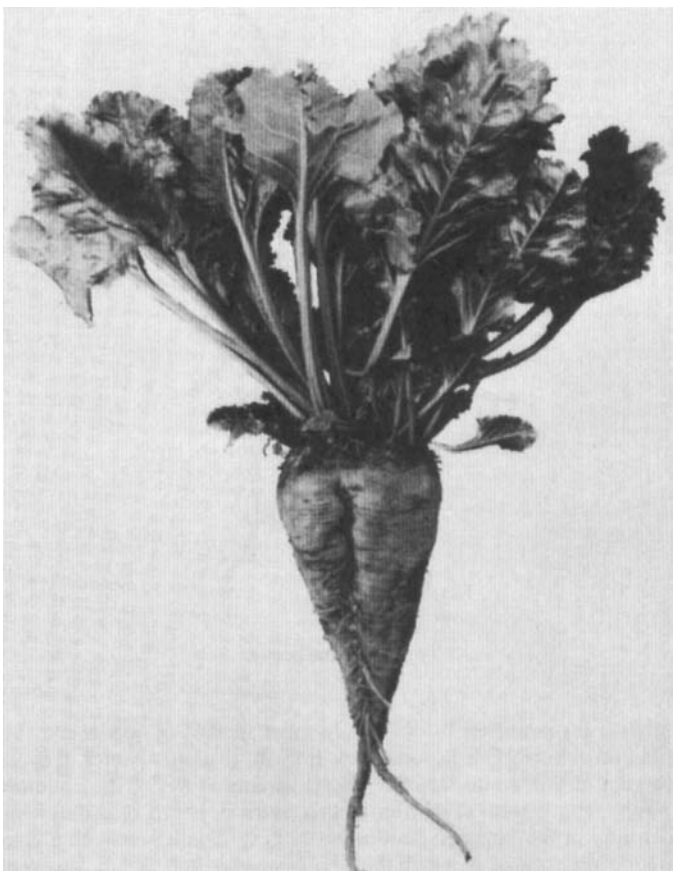

Fig. 1. A sugar beet of desirable shape. (*USDA photo.*)

The sugar beet is a biennial plant which, during its first year of growth, forms a large tapering tap root and a rosette of leaves. At the end of this first year the plant is gathered for sugar production. If allowed to grow the second year, the plant forms a branching stem and an abundance of inconspicuous flowers, utilizing the sugar stored in the root to produce them. See accompanying illustration.

The plant has an elongated tap root which tapers into a long slender root. This may penetrate 4-6 feet (1.2-1.8 meters) into the ground. In size and shape the root is extremely variable. Cut transversely, the root is composed of from six to ten, or even more, concentric zones. Each zone comprises a ring of conducting cells, outside of which is a ring of small cells in turn surrounded by a ring of large cells. The small cells are rich in sugar, while the large cells are primarily water-storage cells. The formation of these zones is a consequence of the formation of a succession of cambium rings, each of which persists for a few weeks.

In preparing the beets for sugar manufacture, the roots are first lifted from the ground, the leaves cut off, and the roots hauled to the factory. Machinery has largely replaced the hand labor formerly required for these tasks. At the factory the beets are washed thoroughly and cut into thin slices. These slices are put into hot water, which extracts the sugar. The sugar solution is next treated with lime, and then precipitated with carbon dioxide: this removes many impurities, which are filtered off. The purified liquor is bleached with sulfur dioxide, and then concentrated by boiling and crystallized under a partial vacuum. From this crude product the molasses is removed by centrifuging, leaving the sugar which is dried and granulated, after which it is ready for the market. In several factories, ion exchange resins are used to remove impurities more thoroughly. This results in a higher grade of sugar.

Many of the waste products of beet sugar production are utilized. The tops are used as a stock food either in the raw condition or after preserving as ensilage. The beet pulp left after extraction of the sugar is also used as a stock food, as is the molasses from the sugar. Often the pulp and molasses are mixed before feeding. Any refuse from the factory may be used as a fertilizer.

In addition to sugar beets, several other varieties of *Beta vulgaris* are known. One of them is the common red table beet, which is eaten either boiled or pickled. When correctly grown it has a minimum of fibrous elements as well as a high sugar content. Most varieties of table beet are deep red in color, in contrast to the white-fleshed sugar beet. Another variety of beet is the Mangel-wurzel or Mangel, of which there are several varieties. They are of large size, have a sugar content varying from 4-8% and are developed principally as a stock food.

BEETLE *(Insecta, Coleoptera).* An order of insects of major economic importance in food production. Some species of beetle are quite specialized and confine their destruction to one or a narrow range of crops as, for example, the Colorado potato beetle, the cucumber beetle, the Mexican bean beetle, the rice leaf beetle, the seed corn (maize) beetle, the stored-grain beetle, and the sweet potato beetle. Other species of beetle destroy a wide variety of plants and crops. These species include the flea beetle, the ground beetle, the grub beetle, and the Japanese beetle. However, some species of ground beetle are considered economically beneficial. See Fig. 1.

Coleoptera is the largest order in the animal kingdom, with almost 200,000 described species. It embraces almost the entire range of adaptation of the class, although very few beetles are parasitic. See also **Coleoptera**.

Beetles are usually recognized by the thickened wing covers that meet in a straight line down the middle of the back. These wing covers, or elytra, are modified forewings. In most species of beetle, they are thickened or horny, but in some they are soft. In some species, they are divergent and in some they are short, leaving much of the abdomen exposed. The typical condition of the elytra is found outside of this order only in the earwigs. Beetles have biting mouth parts and a complete metamorphosis in which the larval stage is often a grub.

Typical of the high degree of specialization found in some beetles is the furniture beetle which lives only in old wood.

Harmless and Beneficial Beetles. The familiar "lady bug" consumes only injurious insects. See also **Beneficial Insects**; and **Lady Bug**. The firefly or lightning bug is a member of *Coleoptera* and is a soft-bodied beetle with a luminous organ in the abdomen. The energy system of the lighting or flashing is of very high efficiency and involves enzyme reactions

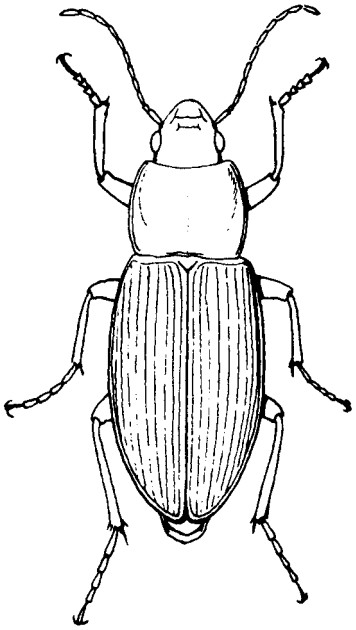

Fig. 1. Typical ground beetle.

with oxygen. No economic value, beneficial or destructive, is attributed to the firefly.

BEEWOLF *(Philanthus bicinctus).* Wasps of the family *Sphecidae*, these voracious insects were so named by the renowned ethologist, Niko Tinbergen, who first made serious studies of these insects in the 1930s. The name derives from the penchant these small insects have for honeybees, their principal prey. Beewolves range from 7 to 22 mm in length. They are brightly colored, with bands of yellow across the abdomen. They are among the most commonly seen wasps, with 34 species living in North America and a total of 136 species throughout the world. The beewolf seeks flowers and nectar because these attract their prey, honeybees. Beewolves are commonly encountered in Grand Teton National Park, Yellowstone National Park, and the Great Sand Dunes of southern Colorado. H.E. Evans (Colorado State University) and K.M. O'Neill (Montana State University) have been studying the habits and habitats of beewolves for nearly two decades. These investigators report that beewolves may be found in "any spot where the soil lends itself to digging — forest clearings, eroded hillsides, dirt paths, sandy pits — often carpeted with the nests of beewolves." Some species of beewolf generalize in terms of their prey, while others specialize — for example, preferring only male sweat bees or bumblebees. Beewolves generally inhabit underground burrows. Although individuals live only about four weeks, a nest at a given location may be active for over 30 years, if left undisturbed. Beewolves sting their victims with a very powerful, paralyzing toxin, this procedure requiring but a few seconds.

As with many insects, the beewolf has its positive and negative contributions. For example, they capture bees that pollinate crop plants and wild flowers, but they also prey on pests such as caterpillars and grasshoppers. A scientist, R.T. Simonthomas (University of Amsterdam) (*http://www.bio.uva.nl/Algemeen/English/english.htm*), has estimated that a female beewolf may capture and kill a thousand honeybees per day. Where the population of beewolves is very great, as in the Dakhla Oasis of Egypt, beekeeping is not possible. Some investigators have suggested that perhaps the beewolf may be helpful in killing off the aggressive Africanized bees that have commenced to invade the southern United States.

Some scientists have found the beewolf of particular interest as a path to observing some of the social aspects of insect life. Also, there is interest in their venom as a potential drug.

BEGGIATOA. A genus of filamentous sulfur bacteria which is capable of converting hydrogen sulfide to sulfuric acid. Sulfur granules are stored in the cells, and may be oxidized to supply the cell with the necessary energy for life. The bacteria are autotrophic in form, using chemosynthesis to obtain energy.

BEIJERNICK, MARTINUS WILLEM (1851–1931). Beijernick was a Dutch microbiologist whose studies of the agent of tobacco mosaic disease, which he termed *contagium vivum fluidum*, yielded important early information for formation of the concept of 'filterable', 'invisible', viruses.

More than two centuries after Anton van Leeuwenhoek was building his microscopes in the back of his draper's shop in Delft, Martinus Willem Beijerinck graduated as a 'Chemical Engineer' from Delft Polytechnic Institute. From a modest non-academic background he rose to make fundamental contributions to the then rapidly developing science of microbiology. A work-obsessed loner who never married and lived with two older sisters, he had one enduring friend from student days: Jan van't Hoff of stereochemistry fame, who in early discussions sowed the seeds of a biochemical approach to microbiological problems in Beijerinck's fertile mind, and to what he himself was later to characterize as 'microbial ecology'. See also **Bacteriology (The History)**; **Leeuwenhoek, Antoni van (1632–1723)**: and **Virology (The History)**.

In the 1890s he became professor of general bacteriology, and then microbiology, in Delft. The laboratory there, and the students of this new 'Delft School', became known for excellence in the wider world. His own research covered a wide range of subjects. Of lasting importance were his studies of anaerobic bacteria, of nitrogen fixation by free-living soil microorganisms, especially *Azotobacter chroococcum* and *Bacillus radicicola*, which he succeeded in cultivating from root nodules of species of *Papilionaceae*. Equally important were his studies of bacterial nutrition which led to what became classic enrichment culture methods.

His study of the agent of tobacco mosaic disease in the late 1890s reflected the chemical knowledge he had absorbed in those early discussions with van't Hoff. In Russia D. I. Ivanovsky had demonstrated the ability of the unknown agent to pass through Chamberland filter candles. Beijerinck independently not only confirmed Ivanovsky's results, but on the basis of further experiments was able to draw a conclusion and form a revolutionary concept, which at the time was treated with a measure of disbelief in the laboratories of the Institut Pasteur in Paris and the Koch Institute in Berlin, where Friedrich Loeffler and Paul Frosch considered the also 'filterable' agent of foot-and-mouth disease, discovered at the same time, to be simply a very small bacterium. Beijerinck coined for the invisible and filterable agent the term *contagium vivum fluidum*, struggling in vain to decide whether it might be a tiny 'corpuscular', 'particulate' substance, or a 'dissolved' molecule of low molecular weight. The complex problem of the nature of viruses was not to be solved until more than half a century later. See also **Foot-and-Mouth Disease**; **Koch, Heinrich Hermann Robert (1843–1910)**; and **Löffler, Friedrich August Johann (1852–1915)**.

LISE WILKINSON, Wellcome Institute for the History of Medicine, London, UK

BEILSTEIN, F. P. (1838–1906). A German chemist noted for his compilation *Handbuch der Organischen Chemie*, the first edition of which appeared in 1880. A multivolume compendium of the properties and reactions of organic compounds, it has been revised several times and remains a unique and fundamental contribution to chemical literature.

BEL. See **Units and Standards**.

BELLADONNA *(Atropa belladonna; Solanaceae).* The plant grows as a native in Europe and in parts of Asia. It is commonly known as Deadly Nightshade. It is about 3 feet (0.9 meter) tall, and has dull green leaves and purple flowers, which are followed by cherry-like red fruits. Every part of the plant contains the poisonous substance for which it is known. This drug atropine is a very poisonous alkaloid obtained principally from the roots and leaves. Belladonna is used medicinally most often as the tincture.

See also **Alkaloids**.

BELLAMY METHOD. A method of estimating horizontal divergence of air, using a triangular network of rawinsonde stations, devised by J. C. Bellamy in the late 1940s.

At any one altitude, the wind measurements at the vertices of the rawinsonde triangle are linearly interpolated along the sides of the triangle to find the average wind component perpendicular to the side. When these normal wind components are multiplied by the length of the respective side, summed over all sides, and divided by the area of the triangle, the result is the average horizontal divergence within the triangle. Note that this method is sensitive to wind measurement errors and to the spacing between rawinsondes. See also **Rawinsonde**; **Winds and Air Movement**.

BELLATRIX *(γ Orionis).* Ranking twenty-fifth in apparent brightness among the stars, Bellatrix has a true brightness value of 2,300 as compared with unity for the sun. Bellatrix is a pale yellow, spectral type B star and is located in the constellation Orion south of the ecliptic. Estimated distance from the earth is 300 light years. See also **Constellations**.

BELL CRANK. A means frequently used to transfer reciprocating motion at right angles is that of a rigid-angled arm pivoted to a fixed point at its vertex, and having hinge connections at its extremities. The bell crank is a type of lever, and the motions of its end are not those of reciprocation, but rather of rotation, but if comparatively long rods are hinged to it, the other ends of those rods will have similar motion. The amplitude of the reciprocation transmitted by the bell crank is directly proportional to the radii from the pivot point to the joints.

BELLOWS. Usually constructed of metal, this mechanical device finds wide application in mechanical, thermal, instrumentation, and control systems. A metal bellows may be defined as a flexible, expansible, and collapsible metal vessel consisting of a series of annular plates having their inner and outer circumferences joined together. The manner in which the plates are joined together depends upon the type of bellows and the method of manufacture. A seamless metal bellows is shown in Fig. 1. Bellows are used in thermal systems where, because of expansion and contraction resulting from temperature changes, flexibility of a leakproof nature must be imparted to piping and other connections. Bellows also are used in situations where flexibility is required because of vibration conditions. A major application for bellows is in the instrumentation field.

Among the more important basic properties of metal bellows are (1) spring rate or flexibility, (2) pressure resistance, (3) mean effective area, and (4) life.

Spring rate. Usually, it is desirable to have the lowest possible spring rate commensurate with other properties important to the application. The spring rate is primarily regulated by the material thickness and is further affected by the material's modulus of elasticity, the depth of corrugations, and the number of free plates in the total length of the bellows.

Pressure resistance. Three generalized statements apply: the maximum pressure resistance is (1) a direct function of the square of the material thickness, (2) an inverse function of the depth of corrugation, and (3) independent of the number of free plates, except that, when the total length of a bellows exceeds its diameter, internal pressure may introduce sidewise distortion or buckling.

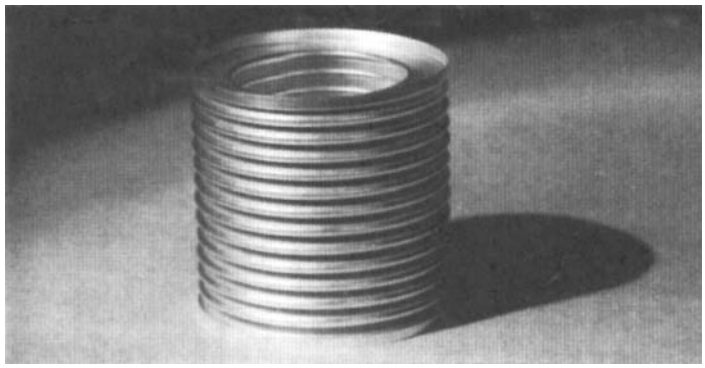

Fig. 1. Metal bellows of type commonly used in instrumentation and control systems. (*Robertshaw*.)

Mean effective area. This affects the ability of the bellows to perform work from changes in pressure. Just as a pressure increase applied to the area of a piston inside a cylinder will produce motion, the pressure applied to the effective area of a bellows will produce thrust. Because of the curved sidewalls of a bellows, the effective area is not quite the exact difference between the area calculated for the extreme outside diameter and that for the extreme inside diameter. A simple expression for calculating the mean effective area of a bellows is

$$\text{Mean effective area} = 0.1963(D + d)^2$$

where $D =$ outside diameter; $d =$ inside diameter. Area, of course, is independent of bellows length.

Life expectancy. There are no easy rules for use in forecasting the useful life of a bellows. Factors that affect life include (1) the safe stress level, (2) the type of metal used, (3) compression or extension from the normal free length, (4) environmental conditions, including corrosive atmospheres, (5) cyclic versus fairly constant pressure changes of the application. Metals commonly used for bellows construction include brass, phosphor bronze, *Monel*, and various stainless steels. The recommendation of a multiple bellows may be in order to obtain maximum pressure resistance at the least expense of spring rate.

Bellows can be used as small pumping devices for handling gases and liquids. For example, such pumps may be used in systems for processing radioactive, hazardous, and rare gases. They also have been used as pumps in commercial aircraft for drinking water pressurization systems. Some metal hose for nuclear applications is, in essence, a high-quality formed bellows restrained axially by steel braid and made from stainless or Inconel materials. Extremely tiny bellows have been used as sensors of intercranial fluid pressures in hydrocephalic infants. By implanting the precision miniature bellows in the skull of such infants, physicians can monitor the pressure of the fluids and possibly prevent brain damage. The fuel tank connection in the space shuttle required a three-joint flexible member providing motion compliance between the tank, structure, and related plumbing. A formed bellows is the key component. The spherical joint includes built-in stops that are internally sealed and loaded by formed bellows. Each joint must withstand pressures from 23.8 atmospheres (operating) to 95.2 atmospheres (bursting) pressures with a useful operating life of 10 years.

BELL'S PALSY. This is a disease of the peripheral nervous system and is one of several manifestations of cranial mononeuropathy. The facial muscles innervated by the seventh cranial nerve are weakened and contribute to this condition. Onset is usually sudden and may be noticed first after a night's sleep. Sometimes patients complain of rather vague sensations or discomfort in the region of cheeks and ears. In some cases chewing and other facial motions may be difficult. Prednisone is used in the initial treatment of the disorder. With several days of treatment, the outlook for recovery is excellent. If the facial nerve does not respond to this drug, electrical stimulation may be attempted. The disorder affects all ages. About 20 persons in 100,000 population are affected by this disorder. See also **Central and Peripheral Nervous Systems**.

BELL TAPER. A process of modifying a time series of data whereby the beginning and ending 10% of the data points are smoothly reduced in

amplitude to approach zero at the ends. Such conditioning of raw data is often necessary before performing a spectral or Fourier analysis. If this were not done, it is possible that spurious spectral signals might be introduced because the Fourier analysis assumes that the finite-duration time series is cyclic (which could cause a step discontinuity between the end of the series and the beginning of the repeated series). However, any time that data are modified, including the conditioning described here, the validity of the resulting analysis may be questioned.

AMS

BEMPORAD FORMULA. A formula for the optical air mass m in terms of the zenith distance z of the sun or other celestial body:

$$m = R/58.36 \sec \sin z$$

where R is astronomical refraction, seconds of arc.

For values of z less than about 70°, the Bemporad formula can be replaced by the simpler approximate formula,

$$m = \sec z$$

BÉNARD CONVECTION CELLS. When a layer of liquid is heated from below, the onset of convection is marked by the appearance of a regular array of hexagonal cells, the liquid rising in the center and falling near the wall of each cell. The criterion for the appearance of the cells is that the Rayleigh number should exceed 1700 (for rigid boundaries).

BENCH MARK. A bench mark is a point of known elevation and location. It is used in surveying as a vertical reference point when finding the elevation of other points of a less permanent nature. The point may be the head of a spike or bolt driven into a tree in such a manner that the top of the head is as nearly horizontal as possible, the highest point on the top of a hydrant, or the top of a flat, noncorrosive plate set securely in stone or concrete. Bench marks may be temporary or permanent, depending upon their use and should be located so that they are easily accessible for instrument work.

BENDING MOMENT. The bending moment at any section of a member is equal to the algebraic sum of all the moments on one side of the section about a centroidal axis of the section. This definition assumes that all of the external forces are coplanar, that is, act in one plane. An internal resisting moment at any section is equal to the sum of the moments of the internal stresses about the gravity axis of the section. The external bending moment acting on any section is numerically equal to the internal resisting moment but acts in the opposite direction. External moments are positive or negative depending upon the direction in which they tend to rotate the section of the beam under consideration. This sign convention is entirely arbitrary although it is customary in beam analysis to assume that positive moments are those tending to shorten the top surface of the beam while negative moments are those which lengthen the top surface. The point on the longitudinal axis of a beam at which the bending moment changes sign is called the point of contraflexure or the point of inflection.

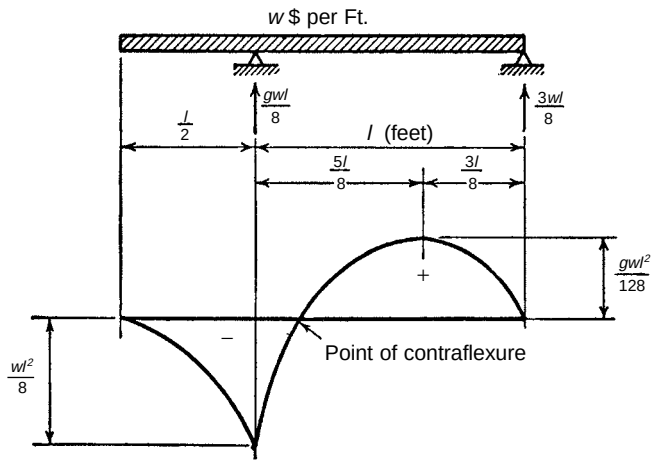

Fig. 1. Bending moment diagram.

Pure bending is a term used to denote the condition where the shear is zero over a finite length. It follows that the bending moment is constant over this length. Bending moments have a very important part in beam action since they cause the flexural stresses (see **Flexure**) and are the principal cause of deflections.

A graphical representation of the variation of bending moment on a beam is called a bending moment diagram. The illustration in Fig. 1 of a bending moment diagram is for an overhanging beam with a uniformly distributed load covering the entire length of the beam. The maximum bending moments are indicated on the diagram occur where the shear changes sign. See **Shear** for the shear diagram for this beam. Since the product of a force and distance is a moment, bending moments are expressed as foot-pounds, kilogram-meters, etc. See also Section **Modulus**; and **Unsymmetrical Bending**.

BENEFICIAL INSECTS. Numerous species of insects contribute in a positive way to increased quantity and quality of food production. An attempt to assign monetary values to these contributions is essentially impractical because there are too many unknown variables beyond quantification. Setting aside aesthetic, medicinal, scientific research, and scavenging roles played by insects, which are valuable but not directly related to food production, the following principal contributions of the beneficial insects include:

1. Destruction of damaging insects and other pests.
2. Pollinization of numerous food plants.
3. Improvement of soil conditions.
4. Destruction of undesired weeds.
5. Production of food products (such as honey).
6. Source of food for fishes and some farm animals and poultry.

Destruction of Damaging Insects. This is possibly the most visible role of the beneficial insects. A few examples include:

Ant-lion (Order *Neuroptera*; family *Myrmeleonidae*). See Fig. 1. Also known as the doodle bug, this is the brown-colored larva of a neuropterous insect which lives at the bottom of a conical-shaped pit in sand or loose

(**a**)

(**b**)

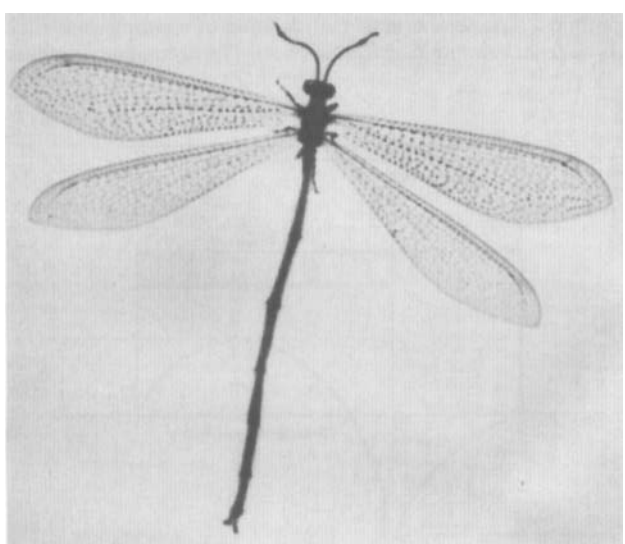

Fig. 1. (**a**) Ant-lion or "doodle bug," (**b**) imago or adult. (*USDA photo*.)

granular soil. The insect is equipped with powerful, spiny jaws. Once the pit is constructed, the insect, about $\frac{1}{2}$-inch (12 millimeters) in length, lies partially buried at the bottom of the pit, awaiting prey to come to investigate the pit. With extremely rapid movements, the ant-lion showers the prey with sand, causing it to fall to the bottom of the pit, at which instant the ant-lion seizes the prey with its powerful jaws. The ant-lion feeds on ants and other insects, many of which are damaging in some way to food crops. The imago adult of the ant-lion larva is a small flying insect with gauzy wings that emerges in the spring, but is seldom seen. During part of the winter, the ant-lion pupates in a silken cocoon. The ant-lion is found in many parts of the United States, but is most abundant in the southern states.

Aphid-lion (Order *Neuroptera*; family *Chrysopidae*). As with the ant-lion, it is the larva of this insect that functions in an economically beneficial way. The larva is a yellowish, or mottled red or brown creature with a long, narrow body that tapers at both ends. It is equipped with large, sickle-shaped jaws. Hairs on the body, which is about $\frac{3}{8}$-inch (9 millimeters) long, are prominent. The adult female lace-winged fly deposits her eggs singly on stems and stalks or leaves of numerous plants, including many food plants adversely affected by aphids. See Fig. 2. Upon hatching, the larva or aphid-lion immediately searches out aphids upon which to feed. The aphid-lion also consumes mealybugs, scales, thrips, and mites–and the eggs of numerous insects. The lacewing adult has gauzy green wings, yellow eyes, fragile antennae, and is quite fragile. Distribution of this beneficial insect is throughout the United States.

Assassin bug (Order *Hemiptera*; family *Reduviidae*). Some species feed on the immature forms of insects. The adult assassin bug is a light-brown insect, from $\frac{1}{2}$- to $\frac{3}{4}$-inch (12 to 19 millimeters) long. See Fig. 3. It walks over plants slowly and clumsily, holding its forelegs in prayer-like position and using them to capture and hold its prey. This insect is distributed throughout the United States. It should be added that certain species of the assassin bug should be viewed in a negative context. Some of these insects can inflict painful bites to human beings and should never be handled. One species is a carrier of Chagas' disease, which occurs in Central and South America.

Damsel bug (Order *Hemiptera*; family *Nabidae*). This insect strongly resembles the assassin bug. It is pale gray, about $\frac{3}{8}$-inch (9 millimeters) long, and uses its forelegs to capture prey. The insect feeds on aphids, fleahoppers, and small larvae of numerous insects. The front legs of the damsel bug appear to be especially modified for grasping prey. Distribution is throughout the United States.

Ground beetles (Order *Coleoptera*; family *Carabidae*). This is a very large family of long-legged beetles, most of which are predaceous, and thus beneficial when in both the adult and larva stages. The adults are usually dull black or brown. The bodies are long and oval, and the heads are narrow. Ground beetles usually are seen on the ground, located under stones of loose trash. The insects hide by day and are active at night, running rapidly when disturbed. The larvae are slender, flattened bodies that taper slightly at the tail. There are two spines or bristles at the rear end. Ground beetles feed on a wide variety of caterpillars and numerous other insects. Because there are so many species, there is a wide variation in size, the length ranging from $\frac{1}{6}$-inch (1.5 millimeters) to about $\frac{2}{3}$-inch (17 millimeters). Not all beneficial species are fully colored, but may display metallic-appearing blue, green, or purple coloration. Usually the upper surface is uniform, with no markings, such as spots or stripes. Ground beetles are distributed throughout the United States.

Lady beetle (Order *Coleoptera*; family *Coccinellidae*). Also called ladybirds and ladybugs, these insects feed on aphids, spider mites, scales, mealybugs, and several other insects. The adult lady beetle is a shiny red or tan. The back is convex and the legs are short. Length ranges from $\frac{1}{16}$-inch to $\frac{1}{4}$-inch (1.5 to 6 millimeters). The body is oval-shaped and may have a black spot on the back. Lady beetles have been imported into regions to achieve specific insect control objectives. An example is the employment of the lady beetle (*Cryptolaemus montrouzieri*) to control the citrus mealybug (*Pseudococcus citri*). Distribution of the lady beetle is throughout the United States. It should be noted that not all members of the family *Coccinellidae* are beneficial. The family also includes the very damaging Mexican bean beetle (*Epilachna varivestis*, Mulsant).

Praying mantis (Order *Orthoptera*; family *Mantidae*). Also called mantid, this insect is quite beneficial and is highly interesting. See Fig. 4. The praying mantis is quite large, ranging from 2.5 to 5 inches (6+ to 12+ centimeters) in length. The insect derives its name from the manner in which it holds and feeds upon its prey. The forelegs are long and powerful and the posture assumed by the insect when eating appears as though it may be praying. This insect feeds on aphids and other small insects when young. The adults can feed on rather large insects when such are available. Studies indicate that the insect is strictly carnivorous. The young mantids hatch in the spring from eggs that have been laid in masses on shrubs or tall grass and covered with a froth that hardens. The young resemble the adults, but are wingless. This beneficial insect is

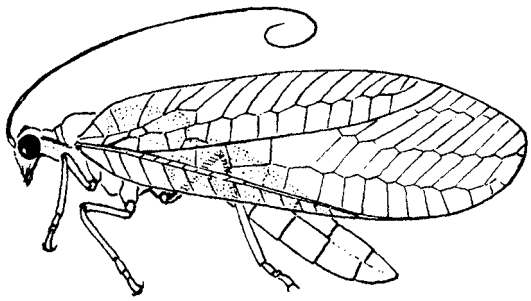

Fig. 2. Lacewing fly, the adult of the aphid-lion. (*USDA photo.*)

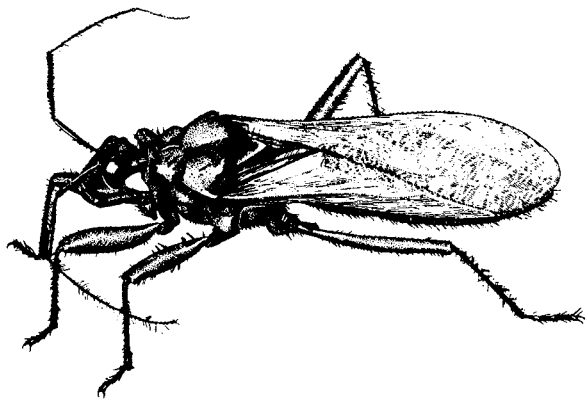

Fig. 3. Adult assassin bug. (*USDA photo.*)

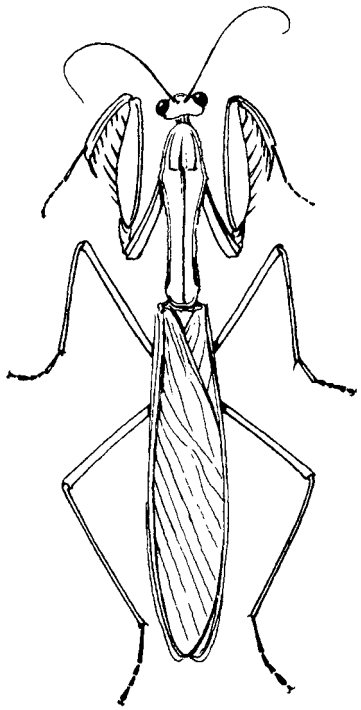

Fig. 4. Praying mantis (also called mantid). (*USDA photo.*)

found throughout the United States, but is most abundant in some of the northeastern states.

Syrphid flies (Order *Diptera*; family *Syrphidae*). Also sometimes called *flower flies* or *sweet flies*, these insects are predaceous in the larval stage. Some observers report that a syrphid fly larva is satiated with juices sucked out of the aphid body. The larvae resemble slugs and are of a brown, gray, or mottled coloration. The adult fly is a bright yellow with black markings and are from $\frac{1}{4}$- to $\frac{3}{8}$-inch (6 to 9 millimeters) in length. In addition to the high rate of aphid destruction per larva, the insects are present in large numbers, at least several hundred per acre under normal circumstances. The syrphid fly larva, of course, consumes other small insects along with aphids.

Wasps and insect parasites. There are several insects, known as *entomophagous parasites*, that function in a similar manner to control insect populations. These insect parasites lay their eggs within the bodies of other insects. As the larvae from these eggs develop within the host, the host is either killed in the process, or greatly damaged, as in some cases, losing its ability to reproduce its own species.

In this group of beneficial insects are the tachinid flies (order *Diptera*; family *Tachinidae*). They appear something like a slightly overgrown housefly, but a detailed inspection reveals numerous differences, including bristles on their antennae. The adult tachinid fly lays her eggs in foliage that is frequented by other insects who may find the eggs attractive as food, or eggs may be fastened to the host insect with a sticky substance. Sometimes larvae that are hatched may be attached to the host. Once it is a part of the host, the larva consumes tissue of the host, instinctively consuming tissue that is not immediately vital to maintenance of life of the host. The host moth or butterfly will prepare a cocoon or chrysalid before it expires. The adult tachinid fly will later emerge from the cocoon, having prevented the host insect from completing its life cycle. Tachinid flies are particularly effective against armyworms. The tachinid species, *Winthermia quadripustulata*, lays eggs on the back of the armyworm. The resulting maggots penetrate through the skin of the worm and kill it within a few days. It is estimated that perhaps half of the armyworm population is destroyed in this manner. The tachinid species, *Lydella stabulans grisescens*, operates just as effectively, but in a more complex cycle, in destroying 50% or more of corn borer larvae.

Other parasitic insects include *Scelionidae* (egg parasites), very small insects that deposit their eggs inside the eggs of other insects. See Fig. 5. An example is *Eumicrosoma beneficia*, which is a parasite of chinch bug eggs. The chalcid wasps, of many species, are effective against a wide range of moths and butterflies. These are described in entry on **Chalcid Wasp**. Tens of thousands of these wasps have been reared and used as biological control tools against the codling moth, oriental fruit moth, and sugarcane borer. The *Encyrtidae* are used in the biological control of certain scale insects. As an example, *Aphycus helvolus* is effective against black scale. The *Aphelinidae* are effective against many insects of *Homoptera*. As an example, *Aphelinis mali* is effective against the woolly apple aphid. And similar examples go on and on — involving the *Pteromalidae*, the *Eulophidae*, the *Ichneumonidae*, and the *Brachonidae*. The latter, for example, is effective against the tomato hornworm caterpillar.

A number of wasps also function in a predaceous manner. The larger wasps, in particular, sting caterpillars, paralyzing the prey and thus making it available as feed for the young.

Pollinization of Food Plants. A second major role of insects in assisting with food production is their function as pollinators. The role of the honeybee is well understood. Plants which are fully or partially dependent upon insects for pollination are thus production of quality fruits and seeds include: alfalfa, apple, bean, blackberry, cherry, clover, cowpea, cranberry, cucumber, eggplant, fig, lemon, melon, orange, peach, pear, pepper, plum, prune, pumpkin, raspberry, soybean, squash, strawberry, sweet clover, and tomato. The dependence of fig on the fig wasp is described in entry on **Chalcid Wasp**.

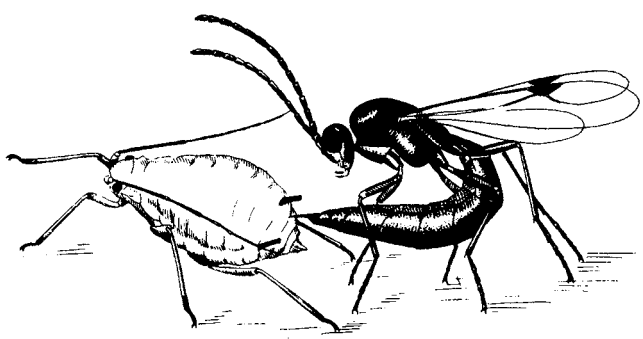

Fig. 5. "Tiny wasp" depositing egg in body of small insect. (*USDA photo.*)

Improvement of Soil Conditions. This beneficial role of insects is more difficult to assess because so many soil insects are damaging and most of the attention has been given to them. But, it is evident, of course, that in their burrowing activities, many insects reach considerable depths (up to several feet or a few meters in some cases) and thus make the soil porous and better equipped for making air, water, and nutrients available to growing plants. Some insects tend to bury organic materials in the soil. Tremendous quantities of insects perish on or in the soil, adding organic matter of their bodies to the total organic content of the soil. While living, they contribute their excreta to the soil. To comprehend these benefits, one must consider the dimensions of the phenomenon. Obviously, the contribution of a single or just a few insects is trivial to the extreme. But to this must be added the dimensions of the billions upon billions of insects that are engaged in such activities.

Production of Food Products. The manufacture of honey by the honeybees is an outstanding example of direct contribution of an insect to food for consumption by human beings. Very important is the source of food provided by insects to support populations of edible fishes. The percentage of insects in total food consumed by some fishes is often high. For example, upon examination, it has been shown that the food content of some fresh water species may run as high as 60% or more of insects consumed by the fish. The larvae maggots, and nymphs of certain insects are particularly attractive to fishes.

People of many cultures also consume insects directly as a food substance, frequently as a delicacy.

BENEFICIAN. See **Coal**; and **Iron**.

BENGUELA CURRENT. See **Ocean Currents**.

BENHAM TOP. A Benham top is a disc bearing characteristic black and white portions, which under certain conditions of angular velocity and illumination induces chromatic responses. See **Fechner Colors**.

BENIGN. A term signifying *nonmalignant*; favorable for recovery. Most frequently used to describe noncancerous tumors.

BENT. A transverse frame that forms an integral part of a structural unit or supports another structural unit is called a bent. Bents are designed to carry lateral as well as vertical loads, and are made of structural steel, reinforced concrete, prestressed concrete, or wood. They are used extensively in connection with viaducts and industrial buildings. Viaduct bents consist of columns held firmly together by bracing in horizontal and vertical planes. Bents in buildings are composed of a roof truss and the supporting columns or of a roof girder rigidly attached to the columns so as to form a rigid frame. The bents support longitudinal beams, commonly called purlins, on which the roof is laid.

BENTHOS. The plants and animals that live on the sea bottom. These include the permanently attached or immobile forms (e.g., sponges, corals, oysters), creeping forms (e.g., crabs, snails), and the burrowing animals (e.g., worms). Barnacles, the larger seaweeds, and sea squirts are also members of this group. One of the three groups into which marine life is generally classified. See also **Ocean**.

BENTONITE. The term applied to altered fine-grained volcanic ashes which have been blown considerable distance from their origin and deposited in marine waters. The resulting material is usually a white, but sometimes a colored, clay-like sediment which may contain bits of volcanic glass but is composed mainly of colloidal silica which will absorb large quantities of water. Since bentonites are wind-blown deposits they are useful as definite datum planes in stratigraphy, especially in helping to determine the contemporaneity of the different facies of marine sediments.

BENZALDEHYDE. [CAS: 100-52-7] C_6H_5CHO, formula weight 106.12, colorless liquid, mp bp $-26\,^{\circ}C$, bp $179\,^{\circ}C$, sp gr 1.046. Sometimes referred to as artificial almond oil or "oil of bitter almonds," benzaldehyde has a characteristic nutlike odor. The compound is slightly soluble in H_2O, but is miscible in all proportions with alcohol or ether. On standing in air, benzaldehyde oxidizes readily to benzoic acid. Commercially, benzaldehyde may be produced by (1) heating benzal chloride $C_6H_5CHCl_2$ with calcium hydroxide, (2) heating calcium benzoate and calcium formate:

$$(C_6H_5COO)_2Ca + (HCOO)_2Ca \longrightarrow 2C_6H_5CHO + 2CaCO_3,$$

or (3) boiling glucoside amygdalin of bitter almonds with a dilute acid.

Benzaldehyde reacts with many chemicals in a marked manner: (1) with ammonio-silver nitrate ("Tollen's solution") to form metallic silver, either as a black precipitate or as an adherent mirror film on glass (but does not reduce alkaline cupric solution, "Fehling's solution"); (2) with rosaniline (fuchsine, magenta) that has been decolorized by sulfurous acid ("Schiff's solution"), restoring the pink color of rosaniline; (3) with NaOH solution, yielding benzyl alcohol and sodium benzoate; (4) with NH_4OH, yielding tribenzaldeamine (hydrobenzamide, $(C_6H_5CH)_3N_2$), white solid, mp $101\,^{\circ}C$, (5) with aniline, yielding benzylideneaniline ("Schiff's base" $C_6H_5CH{:}NC_6H_5$); (6) with sodium cyanide in alcohol, yielding benzoin $C_6H_5 \cdot CHOHCOC_6H_5$, white solid, mp $133\,^{\circ}C$; (7) with hydroxylamine hydrochloride, yielding benzaldoximes $C_6H_5CH{:}NOH$, white solids, antioxime, mp $35\,^{\circ}C$, syn-oxime, mp $130\,^{\circ}C$; (8) with phenylhydrazine, yields benzaldehyde phenylhydrazone $C_6H_5CH{:}NNHC_6H_5$, pink solid, mp $156\,^{\circ}C$; (9) with concentrated HNO_3, yields metanitrobenzaldehyde $NO_2 \cdot C_6H_4CHO$, white solid, mp $58\,^{\circ}C$; (10) with concentrated H_2SO_4 yields metabenzaldehyde sulfonic acid $C_6H_4CHO\,(SO_3H)_2$, (11) with anhydrous sodium acetate and acetic anhydride at $180\,^{\circ}C$, yielding sodium benzoate $C_6H_5CHOONa$ (12) with sodium hydrogen sulfite, forming benzaldehyde sodium bisulfite $C_6H_5CHOHSO_3Na$, a white solid, from which benzaldehyde is readily recoverable by treatment with sodium carbonate solution; (13) with acetaldehyde made slightly alkaline with NaOH, yielding cinnamic aldehyde $C_6H_5CH{:}CHCHO$, (14) with phosphorus pentachloride, yielding benzylidine chloride $C_6H_5CHCl_2$.

Benzaldehyde may be detected by the appearance of a blue color on treating with acenaphthene and H_2SO_4, followed by heating. Benzaldehyde is used (1) as a flavoring material, (2) in the production of cinnamic acid, (3) in the manufacture of malachite green dye.

BENZENE. [CAS: 71-43-2] C_6H_6, formula weight 78.11, colorless, highly flammable liquid that burns with a smoky flame, mp $5.5\,^{\circ}C$, bp $80.1\,^{\circ}C$, sp gr 0.879 ($20\,^{\circ}C$ referred to H_2O at $4\,^{\circ}C$). Sometimes called *benzol*, *phenyl hydride*, or *cyclohexatriene*, benzene is practically insoluble in water (0.07 part in 100 parts at $22\,^{\circ}C$); and fully miscible with alcohol, ether, and numerous organic liquids. Benzene is of large importance industrially, mainly as a starting ingredient of many reactions and as a solvent. The compound also is of much theoretical interest, being the simplest hydrocarbon of the aromatic group. Forming an explosive mixture with air, benzene can be used as a fuel or fuel component for internal combustion engines. Benzene is the first member of a homologous series of compounds, C_nH_{2n-6}. Methylbenzene or toluene, $C_6H_5 \cdot CH_3$, is the only homolog with the formula C_7H_8. Next in order of the homologous series, C_8H_{10}, exists in four isomeric forms, namely, ethylbenzene, $C_6H_5 \cdot C_2H_5$, and ortho-, meta-, and paradimethylbenzene, $C_6H_4(CH_3)_2$. Of the formula C_9H_{12}, eight isomerides are possible. Possible isomerides increase rapidly as the carbon count increases.

Many of the C_nH_{2n-6} series of hydrocarbons occur in coal gas and coal tar, from which they may be extracted. These were the early sources for benzene and related compounds. Much of the benzene currently is produced from petroleum sources. The separation of benzene from coal tar is difficult because of the presence of scores of isomerides with close boiling points. In one process for making high-purity benzene (99.94% or higher) from coke-oven light oil (the cut boiling between $60-150\,^{\circ}C$), the light oil and a stream of hydrogen are heated to reaction temperature and passed through fixed-bed reactors that contain a proprietary catalyst. In this reaction, the non-aromatics present are converted to light hydrocarbon gases. Sulfur compounds present are converted to H_2S. Some de-alkylation of the higher aromatics present also produces benzene in addition to that contained in the feedstock. Vapors from the reactor are cooled and passed to a stabilizer tower where dissolved H_2S and light hydrocarbons (with boiling points lower than benzene) are removed. The bottoms from the stabilizer containing benzene, toluene, and xylene, are clay-treated. Then follows a series of fractionations to produce benzene, toluene, and xylene, in addition to higher-boiling hydrocarbons. If a portion of the hydrocarbons in the product fuel gas is reformed, no external hydrogen is required.

The synthetic production of benzene generally involves the de-alkylation of toluene. In one non-catalytic process, a hydrogen-rich gas is mixed with liquid toluene feed and preheated prior to charging to the reactor. Toluene reacts with the hydrogen to form benzene and methane. The reaction is exothermic. Operating conditions approximate 500–1000 psi and $595-760\,^{\circ}C$. The process provides about 98% yield of benzene. The toluene is recycled.

In a catalytic de-alkylation process, toluene or C_8 aromatics (alkylbenzenes) are fed to a reactor, together with a hydrogen-containing gas. See Fig. 1. The hydrogen source is not critical and may be manufactured hydrogen or off-gas from a reforming or other refining unit. Effluent from the reactor, after cooling, is charged to a separator, from which hydrogen is removed and recycled to the reactor. Liquid phase from the separator is stripped of hydrocarbons (boiling lower than benzene) in a stabilizing column. One further fractionating step yields product benzene overhead. The bottoms from the tower are recycled to the reactor for de-alkylation. Yields of 98% of theoretical are claimed.

In another process, mixtures of aromatics and nonaromatic hydrocarbons comprise the charge. In a first step, aromatics are continuously extracted from the feed by using an aqueous solution of *N*-methylpyrollidone. A multistage countercurrent extraction tower is used. The operation is carried out at modest temperatures and pressures. The rich aromatic extract phase then proceeds to a stripper, where pentane and a part of the benzene are removed overhead and recycled to the extractor. The bottoms from the stripper are free of nonaromatics and enter a second stripper for further

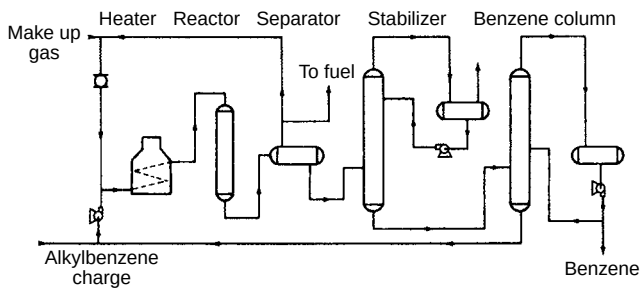

Fig. 1. Process for converting toluene or C_8 aromatic hydrocarbons (catalytic hydrodealkylation) to high-purity benzene. (*UOP, Inc.*)

separation. The distillate from the second stripper contains aromatic-free solvent, which is returned to the extractor. One or more further fractionations yield benzene, toluene, and xylenes of desired specification. A typical feedstock may contain an mixture of aromatics in following ranges: benzene, 26–60%; toluene, 14–22%, xylenes plus ethylbenzene, 15–50%. A similar process uses dimethyl sulfoxide as a solvent.

Styrene is a major consumer of benzene, followed by the production of cyclohexane. At one time, phenol production was the second largest consumer of benzene. Benzene and cyclohexene are closely related economically because cyclohexane can be produced by reacting benzene with hydrogen. Although the foregoing represent the major tonnage uses of benzene, the compound is critically important to the production of hundreds of other compounds. The halogen derivatives of benzene are particularly important. See also **Chlorinated Organics**. These include chlorobenzene, C_6H_5Cl; bromobenzene, C_6H_5Br; benzal chloride, $C_6H_5 \cdot CHCl_2$; benzyl chloride, $C_6H_5 \cdot CH_2Cl$; and benzotrichloride, $C_6H_5 \cdot CCl_3$. Important nitro derivatives of benzene include nitrobenzene, $C_6H_5 \cdot NO_2$; and metadinitrobenzene, $C_6H_4(NO_2)_2$. Amino compounds of large importance derived from benzene include aminobenzene, $C_6H_5 \cdot NH_2$ (aniline); diaminobenzene, $C_6H_4(NH_2)_2$; and triaminobenzene, $C_6H_3(NH_2)_3$.

Phenol, C_6H_5OH, is hydroxybenzene. Resorcinol, catechol, and quinol, $C_6H_4(OH)_2$, may be considered to be dihydroxybenzenes. Pyrogallol and phloroglucinol, $C_6H_3(OH)_3$, may be considered as trihydroxybenzenes. The benzene-related alcohols, aldehydes, and ketones include benzyl alcohol, $C_6H_5 \cdot CH_2 \cdot OH$; benzaldehyde, $C_6H_5 \cdot CHO$; benzoin, $C_6H_5 \cdot CO \cdot CH(OH) \cdot C_6H_5$; salicyaldehyde, $C_6H_4(OH) \cdot CHO$; anisaldehyde, $C_6H_4\ (OHC_3) \cdot CHO$; acetophenone, $C_6H_5 \cdot CO \cdot CH_3$; benzophenone, $C_6H_5 \cdot CO \cdot C_6H_5$; and quinone, $C_6H_4O_2$. The benzene-related acids and salts include benzoic acid, $C_6H_5 \cdot COOH$; ethyl benzoate, $C_6H_5 \cdot COOC_2H_5$, benzoyl chloride, $C_6H_5 \cdot COCl$; benzoic anhydride, $(C_6H_4 \cdot CO)_2O$; benzamide, $C_6H_5 \cdot CO \cdot NH_2$; benzonitrile, $C_6H_5 \cdot CN$; anthranilic acid, $C_6H_4(NH_2) \cdot COOH$; phthalic acid, $C_6H_4(COOH)_2$; phthalic anhydride, $C_6H_4(CO)_2O$; phthalimide, $C_6H_4(CO)_2NH$; isophthalic acid, $C_6H_4(COOH)_2$; terephthalic acid, $C_6H_4(COOH)_2$; benzenehexacarboxylic acid, $C_6H_4(COOH)_6$; and phenylacetic acid, $C_6H_5 \cdot CH_2 \cdot COOH$.

The structure of benzene with its six C–H groups has been known for decades. However, arriving at the ring structure of the compound required much research and imagination in the early days of organic chemistry. Both Kekulé and Dewar and, a bit later, Claus proposed ingenious structures.

Benzene reacts (1) with chlorine, to form (a) substitution products (one-half of the chlorine forms hydrogen chloride) such as chlorobenzene, C_6H_5Cl; dichlorobenzene, $C_6H_4Cl_2$(1,4) and (1,2); trichlorobenzene, $C_6H_3Cl_3$(1,2,4); tetrachlorobenzene (1,2,3,5); and (b) addition products, such as benzene dichloride $C_6H_6Cl_2$; benzene tetrachloride, $C_6H_6Cl_4$; and benzene hexachloride, $C_6H_6Cl_6$. The formation of substitution products of the benzene nucleus, whether in benzene or its homologues, is favored by the presence of a catalyzer, e.g., iodine, phosphorus, iron; (2) with concentrated HNO_3, to form nitrobenzene, $C_6H_5NO_2$; 1,3-dinitrobenzene, $C_6H_4(NO_2)_2$ (1,3), 1,3,5-trinitrobenzene, $C_6H_3(NO_2)_3$ (1,3,5); (3) with concentrated H_2SO_4, to form benzene sulfonic acid, $C_6H_5SO_3H$, benzene disulfonic acid, $C_6H_4(SO_3H)_2$(1,3), benzene trisulfonic acid, $C_6H_3(SO_3H)_3$ (1,3–5); (4) with methyl chloride plus anhydrous aluminum chloride (Friedel-Crafts reaction) to form toluene, monomethyl benzene, $C_6H_5CH_3$; dimethyl benzene $C_6H_4(CH_3)_2$; trimethyl benzene, $C_6H_3(CH_3)_3$; (5) with acetyl chloride plus anhydrous aluminum chloride (Friedel-Crafts reaction) to form acetophenone (methylphenyl ketone), $C_6H_5COCH_3$. BENZIDINE REACTION. A test for blood (hemoglobin) made by acidifying the sample with glacial acetic acid, extracting with ether, and treating the ethereal extract with a solution of benzidine in glacial acetic acid, to which hydrogen peroxide has been added. In the absence of certain metals, a blue or green color, changing to deep blue or purple, indicates the presence of blood.

BENZIDINE REARRANGEMENT. See **Rearrangement (Organic Chemistry)**.

BENZIL REARRANGEMENT. See **Rearrangement (Organic Chemistry)**.

BENZINE. A product of petroleum boiling between 120 °F and 150 °F (49–66 °C) and composed of aliphatic hydrocarbons. Not to be confused with benzene, which is a single chemical compound and an aromatic hydrocarbon.

BENZOIC ACID. [CAS: 65-85-0] $C_6H_5 \cdot COOH$, formula weight 122.12, white crystalline solid, mp 121.7 °C, bp 249.2 °C, sublimes readily at 100 °C and is volatile in steam, sp gr 1.266. Sometimes referred to as phenylformic acid, the compound is insoluble in cold H_2O, but readily soluble in hot H_2O, or in alcohol or ether. Commercially, benzoic acid finds major use as a starting or intermediate material in various industrial organic syntheses, notably in the preparation of the high-tonnage chemical, terephthalic acid. See also **Terephthalic Acid**. Benzoic acid forms benzoates: e.g., sodium benzoate, calcium benzoate which, when heated with calcium oxide, yields benzene and calcium. With phosphorus trichloride, benzoic acid forms benzoyl chloride C_6H_5COCl, an important agent for the transfer of the benzoyl group (C_6H_5CO-). Benzoic acid reacts with chlorine to form *m*-chlorobenzoic acid and reacts with HNO_3 to form *m*-nitrobenzoic acid. Benzoic acid forms a number of industrially useful esters, including methyl benzoate, ethyl benzoate, glycol dibenzoate, and glyceryl tribenzoate.

Although benzoic acid occurs naturally in some substances, such as gum benzoin, dragon's blood resin, Peru and Tolu balsams, cranberries, and the urine of the ox and horse, the product is made on a large scale by synthesis from other materials. Benzoic acid can be prepared from toluene and air in a process that takes place in the liquid-phase in a continuous oxidation reactor operated at moderate pressure and temperature: $C_6H_5 \cdot CH_3 + 1\frac{1}{2}O_2 \rightarrow C_6H_5 \cdot COOH + 2H_2O$. The acid also can be obtained as a byproduct of the manufacture of benzaldehyde from benzal chloride or benzyl chloride.

See also **Antimicrobial Agents (Foods)**.

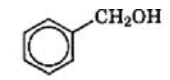
BENZOIN. [CAS: 114-53-9] The term benzoin is used in botany to denote a tree (*Styrax benzoin*) and a resin obtained from it. The former is a tall, quick-growing tree native to Sumatra and Java. The tree has alternate entire leaves, the lower surface of which is soft and hairy, the upper smooth. The flowers are borne in compound axillary racemes; the fruit is a drupe. The resin is obtained by making incisions in the bark. From these a thick white juice exudes and hardens. This is scraped off. It is a soft fragrant substance either white or of yellowish color.

Frequently confused with this is the North American shrub *Benzoin aestivale*, often called Spice bush, which blossoms very early in the spring. All parts of the shrub contain an aromatic substance, which is very noticeable when the plant is bruised.

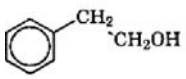
In chemistry, benzoin is a compound obtained from the resin described above, or obtained synthetically. When benzaldehyde C_6H_5CHO is warmed with sodium cyanide dissolved in alcohol, benzoin C_6H_5CO-$CHOHC_6H_5$ white solid, 137 °C, is formed, and has the characteristics of a ketone and a secondary alcohol.

BENZOYL CHLORIDE. See **Chlorinated Organics**.

BENZYL ALCOHOL AND β-PHENETHYL ALCOHOL. Benzyl alcohol [CAS: 100-51-6]. (**1**) β-phenethyl alcohol (**2**) (2-phenylethanol) are the simplest of the aromatic alcohols, and, as such, are chemically similar. Their physical properties are given in Table 1.



(1)



(2)

TABLE 1. PHYSICAL PROPERTIES OF BENZYL ALCOHOL AND β-PHENETHYL ALCOHOL

Property	Benzyl alcohol	β-Phenethyl alcohol
CAS Registry Number	[100-51-6]	[60-12-8]
Molecular formula	C_7H_8O	$C_8H_{10}O$
Mp, °C	−15	−25.8
Bp at 101.3 kPa[a]	205.4–205.7	219.5–220
Bp at 1.33 kPa[a], °C	89.0–89.5	99–100
	1.0441	1.017
Flash point, closed cup, °C	100.4	
Open cup, °C	104.4	
Autoignition temp, °C	436	
Vapor density (air = 1)	3.7	
Vapor pressure at 58 °C, kPa[a]	0.133	0.133
100 °C, kPa[a]	2.02	1.33
Surface tension at 20 °C, mN/m(=dyn/cm)	39	
80 °C, mN/m(=dyn/cm)	33	
Viscosity at 25 °C, mPa · s(=cP)	5.05	7.58
Solubility at 25 °C, water	1 g/25 mL	1 g/51 mL
501 g/1.5 mL	1 g/1.7 mL	

[a] To convert kPa to mm Hg, multiply by 7.5., °C.

Benzyl Alcohol

Benzyl alcohol (**1**) occurs widely in essential oils both as the free alcohol, and, more importantly from a fragrance standpoint, in the form of various esters. Although benzyl alcohol itself is rather bland in odor, combined with its much more fragrant esters it is an important part of the door of jasmine, ylang-ylang, gardenia, some rose varieties, narcissus and peony, as well as castoreum, balsams of peru and tolu, and propolis. Benzyl alcohol occurs primarily in flower oils and tree exudates.

Benzyl alcohol readily undergoes the reactions characteristic of a primary alcohol, such as esterification and etherification, as well as halide formation. In addition, it undergoes ring substitution. In the presence of acid, polymerization is observed, and the alcohol can be thermally dehydrated to toluene [CAS: 108-88-3]. Catalytic oxidation over copper oxide yields benzaldehyde; benzoic acid is obtained by oxidation with chromic acid or potassium permanganate. Catalytic hydrogenation of the ring gives cyclohexylmethanol [CAS: 100-49-2].

Today benzyl alcohol is almost universally manufactured from toluene which is first chlorinated to give benzyl chloride [CAS: 100-44-7]. This is then hydrolyzed to benzyl alcohol by treatment with aqueous sodium carbonate.

In the future it may be possible to oxidize toluene microbially to produce benzyl alcohol. Treatment of toluene in the presence of air with a culture of *M. thermophila* in a phosphate buffer is reported to yield a mixture of benzaldehyde, benzyl alcohol, and *p*-cresol [CAS: 106-44-5].

In the soap, perfume, and flavor industries benzyl alcohol is primarily used in the form of its aliphatic esters. Benzyl benzoate [CAS: 120-51-4] finds widespread use as a fragrance diluent. Benzyl alcohol is frequently employed in bar soap fragrances at 30–40 wt % of the fragrance. Benzyl alcohol is commercially available in five grades.

The largest proportion of benzyl alcohol is for use in the photographic and textile industries although the latter use has been declining. The photo grade is used in a developing bath for color motion pictures, for the development of color transparencies, as a dispersing reagent for silver halide grains in mixed packet emulsions, as a stop bath for production of lithographic plates, as a dispersing agent and film softener in an antistatic treating compound, and as an activator in a print-out image method. The textile grade is used as a dyeing assistant for wool and nylon.

The NF and reagent grades are employed in pharmaceutical industry which makes use of benzyl alcohol's local anesthetic, antiseptic, and solvent properties. It also finds use in cough syrups and drops; ophthalmic solutions; burn, dental, and insect repellant solutions and ointments; and dermatological aerosol sprays. It is used in nail lacquers and as a color developer in hair dyes by the cosmetics industry, and in acne treatment preparations.

Because of its strong polarity and limited water solubility, the technical grade of benzyl alcohol is used in rug cleaners as a degreasing agent, in leather dyeing, in ballpoint inks, as a cleaner for soldering, and as an extractive distillation solvent for xylenes and cresols. It is used as a stabilizer in insecticidal formulations by the agriculture industry and in treating fruits and vegetables. In addition, benzyl alcohol is used extensively in the polymer industry and in the manufacture of automobile tires.

This material has a Generally Recognized As Safe (GRAS) status indicated by the Flavor and Extract Manufacturers' Association for use in flavors and by the Council of Europe for use as a flavor. Benzyl alcohol satisfies the most current guidelines published by the International Fragrance Association (IFRA) which governs the use of fragrance materials.

β-Phenethyl Alcohol

Of all the aromatic organic molecules β-phenethyl alcohol (PEA) (**2**) is probably the most prestigious aroma chemical in the world of perfumery. This is because of its exquisite odor of natural rose petals.

Twenty-four years before its detection in nature PEA was first synthesized in 1876 by reducing phenylacetaldehyde [CAS: 122-78-1] with sodium amalgam. Then, in 1900, it was independently identified in otto of rose and rose water. Subsequently, PEA has been identified in numerous flower oils such as ylang-ylang, narcissus, hyacinth, lily, neroli, and geranium as well as various other natural products like tea, tobacco, orange juice, beer, cigarette smoke, etc.

Physical properties of PEA are shown in Table 1. The pure compound is extremely difficult to crystallize because it tends to supercool to a glass. In addition, it forms a number of azeotropes.

The compound undergoes the usual chemical reactions of alcohols or aromatic compounds.

In insect control, PEA has been considered as a mosquito repellant, and its acetate has been used as an ingredient in Japanese beetle bait. The alcohol also has bacteriostatic action and antifungicidal properties, and it has been claimed as a surface-active agent.

Because of factors of low cost, stability, and odor quality, PEA is ideally suited for use in bar soap fragrances, where its use can be up to 30–50% of the fragrance.

Current commercial methods for making PEA include Grignard synthesis, Friedel-Crafts process, and catalytic hydrogenation of styrene oxide.

Future methods of production include catalytic air oxidation and microbiological oxidation.

Purification problems are primarily solved by two methods: continuous vacuum fractionation and chemical combination to yield a high boiling ester, separation of the noncombining impurities by distillation, and hydrolysis of the ester.

The use of β-phenethyl alcohol generally presents no health problems. This material has Generally Recognized As Safe (GRAS) status as indicated by the Flavor and Extract Manufacturers Association and is approved by the U.S. Food and Drug Administration and the Council of Europe for use in flavors. PEA satisfies the most current guidelines published by the International Fragrance Association (IFRA), which governs the use of fragrance materials.

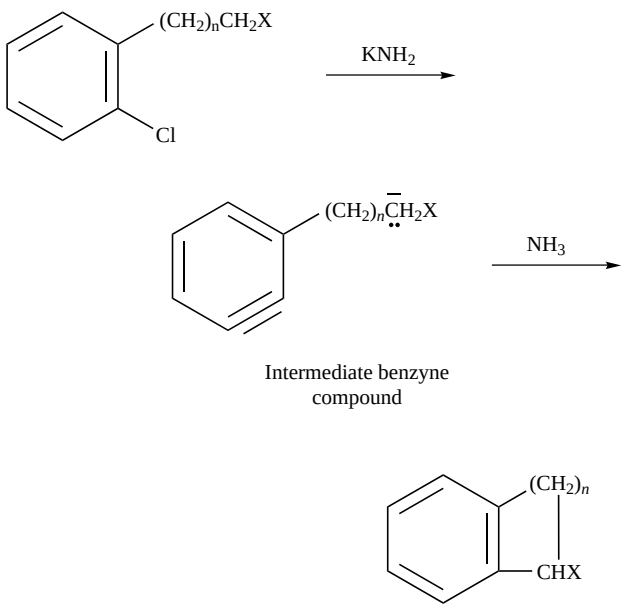
BENZYL BENZOATE. [CAS: 120-51-4] A water-white liquid with formula $C_6H_5CH_2OOCC_6H_5$. Sharp, burning taste with faint aromatic odor. Supercools easily. Insoluble in water and glycerin; soluble in alcohol, chloroform, and ether. B.p. 325 °C, mp 18.8 °C, flash point,

$\sim$150 °C. This compound is produced by the Cannizzaro reaction from benzaldehyde, by esterifying benzyl alcohol with benzoic acid, or by treating sodium benzoate with benzyl chloride. It is purified by distillation and crystallization. Benzyl benzoate is used as a fixative and solvent for musk in perfumes and flavors, as a plasticizer, miticide, and in some external medications. The compound has been found effective in the treatment of *scabies* and *pediculosis capitis* (head lice, *Pediculus humanus* var. *capitis*).

BENZYL CHLORIDE. See **Chlorinated Organics**.

BENZYNE. The concept of benzyne intermediates has largely stemmed from work by Georg Wittig of the University of Heidelberg, Germany, and J.D. Roberts of the California Institute of Technology. Roberts postulated that benzynes form when a substituted benzene (such as bromobenzene) reacts with a nucleophilic reagent, such as potassium amide in liquid ammonia. He and other workers have shown that strong nucleophiles add readily to arynes. If the nucleophile is attached to a side chain on the aryne, a new ring fused to the original aromatic nucleus forms by intramolecular addition. This was shown by Bunnett and B.F. Hrutfiord and also by R. Huisgen and co-workers of the University of Munich, Germany. In this work, heterocyclic compounds were usually obtained. However, in later work J.F. Bunnett and J.A. Skorez, then at Brown University, used the synthesis to obtain homocyclic ring closures, producing derivatives of such compounds as benzocyclobutene, indane, tetralin and benzocycloheptane. Their type reaction may be written as



Intermediate benzyne compound

where $n = 1, 2, 3,$ or 4 $X =$ cyano, acyl, carbethoxy or sulfonyl.

Lester Friedman and Francis M. Logullo prepared substituted benzynes by diazotizing substituted anthranilic acid. This is a mild, room-temperature reaction which permits simultaneous reactions of the benzynes with suitable acceptors to prepare halogen. $-NO_2$, $-CH_3$, and $-OCH_3$ derivatives. They have also prepared new heterocyclic arynes, such as 3-pyridine from 3-amino-isonicotinic acid.

BeppoSAX (Satellite). BeppoSAX is a major program of the Italian Space Agency (ASI) in collaboration with the Netherlands Space Agency (NIVR). The original name, SAX, is the acronym for *Satellite per Astronomia X*, Italian for X-Ray Astronomy Satellite. SAX was launched on April 30, 1996 and renamed BeppoSAX in honor the Italian physicist Giuseppe "Beppo" Occhialini, known for his contribution to the discovery of the PI meson decay and study of cosmic rays. Coincidentally, another X-ray mission, the NASA X-ray Timing Explorer (XTE) operated simultaneously with BeppoSAX, was renamed after launch as Rossi-XTE after another Italian physicist, Bruno Rossi, a pioneer of X-ray astronomy. In a sadder coincidence, the two physicists died in 1993 within weeks of each other. As in real life the two physicists were long-life friends and colleges, the satellites named after them have in several occasion worked in tandem. See also **Rossi X-Ray Timing Explorer (RXTE)**.

BeppoSAX was one of the three projects proposed in 1981 to the Piano Spaziale Nationale (PSN), the Italian organization in charge of the space activities at that time. Selected in 1982, the mission had a major set back after Challenger disaster in 1986. The initial configuration foresaw SAX to be launched via the NASA Shuttle and boosted into the final orbit by the IRIS (Italian Research Interim Stage). With no Shuttle available, the mission had to be redesigned to fly with a Atlas Centaur rocket, with a simplified boost into final orbit, but the scientific objectives were unchanged. The payload was conceived and planned under the responsibilities of a consortium of Italian and Dutch institutes and the Space Science Department of ESA. The 1990s saw the realization of the project, finally launched from Cape Canaveral in 1996 under the supervision of the newly born Italian Space Agency (ASI). The mission was approved for two years, with an estimated duration of four years. (see Fig. 1).

The main scientific goals of BeppoSAX were to obtain broad band spectroscopy for a variety of X-ray stellar objects and to study transient phenomena and long-term monitoring variability of galactic and extragalactic sources. These motivations were complementary to those of missions scheduled for the late 1980s, e.g., ROSAT, GINGA, and RXTE. To achieve the science goals the payload consisted of several instruments. With a field of view (FOV) of 20×20 degrees, corresponding to 5% of the sky, the wide field cameras (WFC), instruments similar in concept to a pin-hole camera, were designed to give alerts to any transient phenomena. Perpendicularly to the WFC were the narrow field instruments, with a FOV up to 1 degree, covering the largest X-ray energy range ever flown (0.1−300 keV) optimized for spectroscopy and high resolution imaging.

After a commissioning and science verification phase of six months, in 1997 BeppoSAX made the press for solving one of the most intriguing mystery of the modern astronomy: gamma ray bursts (GRB). These powerful events were discovered in 1960s by the Vela spy satellites, whose purpose was to search for nuclear bomb detonations. GRBs are very energetic and brighten the gamma ray sky only for a few seconds. Their energy distribution peaks at hundreds of keV in the gamma ray band, but it also extends in the soft X-ray band. Since then several other missions have routinely registered these powerful events without determining where in the sky they occurred. The current generation of gamma-ray detectors has a poor position determination (about 1 degree). On the contrary X-ray detector can determine position with an arcminute position sufficient to make an identification in the sky. See also **Cosmic Rays**.

The poor knowledge of this phenomena divided the astronomers in two camps: those who believed that the source of these explosions was relative nearby occurring within Earth's galaxy and those who supported the idea that they were taking place outside the our Galaxy. BATSE, (Burst and Transient Source Experiment) one of the instruments on Compton Gamma Ray Observatory (CGRO) 1991−2000, detected one GRB per day. This demonstrated that the GRBs were uniformly distributed in the sky, suggesting an extragalactic model. However, because of the low accuracy of their position determination, it has never been possible to link the burst with any known astronomical object and without a firm identification both theories were still viable. See also **Gamma-Ray Astronomy**; and **Compton Gamma Ray Observatory (CGRO)**.

BeppoSAX finally made the link between these GRB events to objects observed in the X-ray regime, named "afterglows," subsequently located in the optical sky. Two important factors contributed to the BeppoSAX success in the identification of the GRB. These factors were combination of the wide and narrow field of view and the broad band pass of the on-board instrumentation. A team of dedicated astronomers and engineers who optimized the satellite ground operations to obtain the rapid response necessary to follow the GRBs helped in this success.

During the night of February 28, 1997, the GRB monitor on BeppoSAX detected an event in a direction included in the WFC instrument. Real-time analysis of WFC data revealed a bright object, whose position was determined with only 3 arcminutes uncertainty, located in the Orion constellation. The satellite was re-pointed at that position with the high sensitivity narrow field instruments within 8 hours of the discovery. The X-ray image showed an object that was fading away with time. The refined position was distributed to ground-base telescopes and the 4.2 m William Herschel telescopes at the Canary Islands detected a faint object with a position consistent with that obtained by the BeppoSAX WFC. In a few hours BeppoSAX made two discoveries: the location of a GRB event with an unprecedented position determination and the discovery of an X-ray

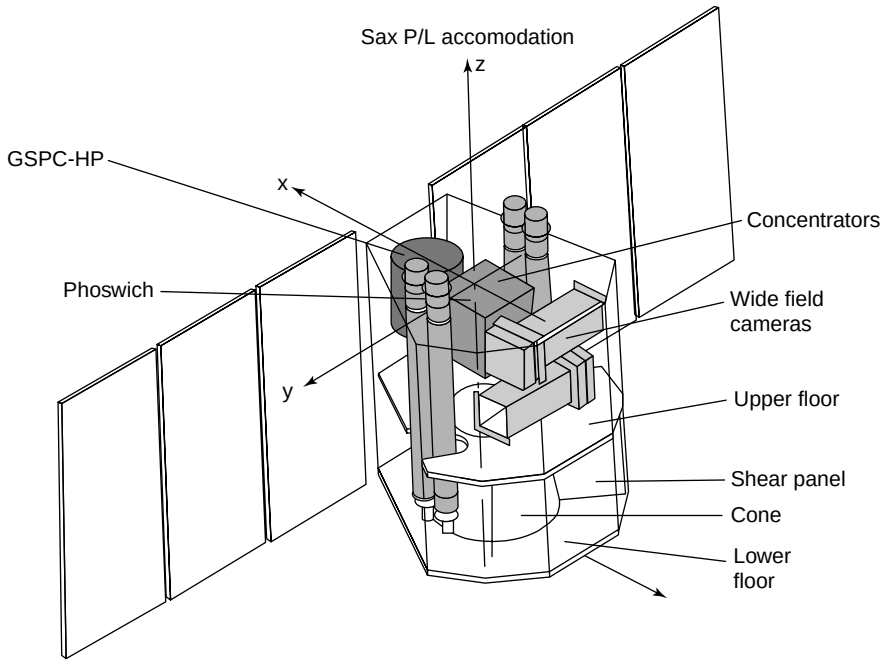


Fig. 1. SAX P/L Accomodation (*NASA/GSFC*.)

event associated with the GRB position that with time was decreasing in intensity. To confirm that, on March 3, 1997, BeppoSAX made another observation at that position. The X-ray object had an intensity 20 times less compared to the first observation. This new phenomena was named "afterglow." See also **Afterglow**.

Up to now about 28 GRB have been detected and followed by BeppoSAX and ground telescopes. Still many questions remain to be answered on the nature of the GRB, but the framework set by BeppoSAX, rapid response and broad band instrumentation, prompted a new NASA mission called Swift. Swift will be launched in 2003. Swift will be dedicated to the study of the GRB and their afterglows. After few years, BeppoSAX is still operating with more than 80% of the payload, The mission operations were extended to May 2001. See also **X-Ray Astronomy**.

BERGAMOT OIL. An essential oil produced from the rind of the fruit of *Citrus aurantium* or *C. bergamia*, relatives of the orange and lemon. The small trees are cultivated in southern Europe. The oil is expressed from the skin of the small yellow fruits and sometimes is used as a scent for cosmetics. The oil also is used sometimes as a clearing agent in the preparation of material for microscopic examination.

BERGERON-FINDEISEN PROCESS. (Commonly called the ice process of precipitation, and formerly, ice-crystal theory; also Bergeron–Findeisen–Wegener process or theory, and with the names in a different order.) A theoretical explanation of the process by which precipitation particles may form within a mixed cloud (composed of both ice crystals and liquid water drops). The basis of this theory is the fact that the equilibrium vapor pressure of water vapor with respect to ice is less than that with respect to liquid water at the same subfreezing temperature. Thus, within an admixture of these particles, and provided that the total water content were sufficiently high, the ice crystals would gain mass by vapor deposition at the expense of the liquid drops that would lose mass by evaporation. Upon attaining sufficient weight, the ice crystals would fall as snow and very likely become further modified by accretion, melting, and/or evaporation before reaching the ground. This theory was first proposed by T. Bergeron in 1933, and further developed by W. Findeisen. Certain of its features related to nucleation had been suggested by A. Wegener as early as 1911. Operation of this process requires numerous small water drops that are supercooled, which is a common feature in clouds between about 0° ($32\,^\circ$F) and $-20\,^\circ$C ($-4\,^\circ$F) or below, along with a small number of ice crystals. The crystals grow by vapor deposition at a rate (maximum at about $-12\,^\circ$C ($-10\,^\circ$F) to give individual snow crystals in some 10 to 20 minutes. Much cloud seeding is based upon the introduction of artificial ice nuclei to supply more of the ice particles. See also **Cloud Seeding**.

BERGIUS, FREDERICK (1884–1949). A German chemist who won the Nobel Prize in 1931 with Carl Bosch for chemical high-pressure methods. He invented a method of converting coal dust into oil via pressurized hydrogen. He also invented a method for production of cattle feed and sugar from wood by hydrolysis. He was educated in Poland and Germany.

BERGIUS PROCESS. Formation of petroleum-like hydrocarbons by hydrogenation of coal at high temperatures and pressures (e.g., $450\,^\circ$C and 300 atm) with or without catalysts; production of toluene by subjecting aromatic naphthas to cracking temperatures at 100 atm with a low partial pressure of hydrogen in the presence of a catalyst.

BERG, PAUL (1926–). An American molecular biologist who won the Nobel Prize for chemistry in 1980 with Frederick Sanger and Walter Gilbert. Berg's research concerned the biochemistry of nucleic acid, particularly regarding recombinant DNA, that is combining a molecule DNA's from different species. His Doctorate was attained at Western Reserve, and later he performed research at Stanford University.

BERKELIUM. [CAS: 7440-40-6] Chemical element, symbol Bk, at. no. 97, at. wt. 247 (mass number of the most stable isotope), radioactive metal of the *Actinide* series, also one of the *Transuranium* elements. All isotopes of berkelium are radioactive; all must be produced synthetically.

The element was discovered by G.T. Seaborg and associates at the Metallurgical Laboratory of the University of Chicago in 1949. At that time, the element was produced by bombarding ^{241}Am with helium ions. ^{247}Bk is an alpha-emitter and may be obtained by alpha-bombardment of ^{244}Cm, ^{245}Cm, or ^{246}Cm. Other nuclides include those of mass numbers 243–246 and 248–250. Probable electronic configuration:

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 6d^{10} 5f^9 6s^2 6p^6 7s^2$$

Ionic radius Bk^{+3}, 0.99 Å. Longest-lived isotope, ^{247}Bk($t_{1/2} = 700$ years).

Berkelium is known to exist in aqueous solution in two oxidation states, the (III) and the (IV) states, and the ionic species presumably correspond to Bk^{+3} and Bk^{+4}. The oxidation potential for the berkelium(III)-berkelium(IV) couple is about −1.6 V on the hydrogen scale (hydrogen-hydrogen ion couple taken as zero).

The solubility properties of berkelium in its two oxidation states are entirely analogous to those of the actinide and lanthanide elements in the corresponding oxidation states. Thus in the tripositive state such compounds as the fluoride and the oxalate are insoluble in acid solution, and the tetrapositive state has such insoluble compounds as the iodate and phosphate in acid solution. The nitrate, sulfate, halides, perchlorate, and sulfide of both oxidation states are soluble.

The first compound of berkelium of proven molecular structure was isolated in 1962 by Cunningham and Wallman. A small quantity (0.004 microgram) of berkelium (as berkelium-249) dioxide was used to determine structure by x-ray diffraction.

Berkelium metal exists in two crystal modifications. Melting point of crystals has been estimated at 986 °C. The first production of berkelium required the solution to several problems in high energy physics. These included the necessity to synthesize the highly radioactive target elements used; safe handling procedures for the high levels of radioactivity encountered had to be developed; new systematics for predicting the modes of decay and half-lives of the still undiscovered isotopes were needed. See also **Chemical Elements**.

BERM (Beach). An impermanent, low, almost horizontal (or landward sloping) shelf, ledge, narrow terrace or bench on the back shore of a beach. Usually formed by material cast up and deposited by storm waves and bounded on one side by a beach scarp or beach ridge. A beach may have no berms, one, or several berms.

BERM (Geology). A relatively flat erosion surface brought to grade during a previous cycle of erosion. The term was introduced by Bascom in 1931. It was intended to replace *strath*, although as used, the term *berm* sometimes includes the shoulder of a new valley, together with the remnant of the old valley floor. The term also is used to describe a horizontal ledge of land bordering either bank of a river, as in the case of the Nile River, which inundates the ledge when the river overflows.

BERM (Structural). A narrow shelf, ledge, bench or strip (horizontal) constructed along an embankment, located part way up and thus breaking the continuity of the slope. The term also is used to describe the margin, side, or shoulder of a road that is adjacent to and outside the paved portion.

BERMUDA HIGH. See **Meteorology**.

BERNAL-FOWLER RULES. The set of rules describing the arrangement of hydrogen atoms in an "ideal" ice crystal. See also **Ice Crystal**. These rules are 1) Each water molecule is oriented such that its two hydrogen atoms are directed approximately toward two of the four surrounding oxygen atoms (arranged almost in a tetrahedron); 2) only one hydrogen atom is present on each O-O linkage; and 3) each oxygen atom has two nearest neighboring hydrogen atoms such that the water molecule structure is preserved. Violations of these rules lead to structural defects in ice, responsible, among other things, for its electrical conductivity and its long (10^{-4} s) electrical relaxation time. See also **Relaxation Time**.

BERNOULLI, DANIEL (1700–1782). Bernoulli came from a Swiss family famous for their scientific and mathematical contributions. His father, Johann (Jean), was famous for his work on integral and exponential calculus and was the founder of calculus of variations. Daniel Bernoulli is often called the first mathematical physicist. He is given recognition for extending calculus to new applications. He is best known for showing that pressure in a fluid decreases as its velocity increases. This is Bernoulli's principle.

See also **Aerodynamics and Aerostatics**; **Bernoulli Equation**; **Bernoulli Law**; **Bernoulli Method**; **Bernoulli Number and Polynomial**; and **Bernoulli Theorem**.

J. M. I.

BERNOULLI EQUATION. A first-order nonlinear differential equation

$$y' + f(x)y = g(x)y^n$$

It may be made linear by the change of variable $y = u^{1/1-n}$ giving

$$u' + (1-n)f(x)u = (1-n)g(x)$$

The equation was offered for solution by Jacob Bernoulli in 1695. It was solved by Leibniz, as indicated here, and by John Bernoulli (1667–1748), brother of Jacob, who separated the variables by using two new ones. See **Bernoulli Number and Polynomial**.

BERNOULLI LAW. A relationship that expresses the conservation of momentum in fluid flow. The usual form applies to the steady non-viscid flow of an incompressible fluid and can be obtained by integrating the Navier-Stokes equations along a streamline,

$$gz + \frac{p}{\rho} + \frac{1}{2}u^2 = \text{constant on a streamline}$$

If the flow is irrotational so that the fluid velocity is the gradient of a scalar potential ϕ, the restriction to steady flow may be removed and the law is

$$\frac{\partial \phi}{\partial t} + \frac{p}{\rho} + \frac{1}{2}u^2 + gz = \text{constant anywhere in the fluid}$$

Lastly, if the fluid is barotropic, i.e., the density is a function of pressure alone, it takes the form,

$$\int \frac{dx}{\rho} + \frac{1}{2}u^2 = \text{constant}$$

valid along a streamline for steady flow. For a perfect gas, with p proportional to ρ^γ,

$$gz + \frac{\gamma}{\gamma - 1}\frac{p}{\rho} + \frac{1}{2}u^2 = \text{constant}$$

The quantity,

$$p\left(1 + \frac{1}{2}\frac{\gamma - 1}{\gamma}\frac{\rho^2}{p}\right)^{\gamma/(\gamma-1)}$$

is known as the total head or stagnation pressure. For flow at small Mach numbers, i.e., $u^2 \ll \gamma p/\rho = \gamma RT$, it is $p + \frac{1}{2}\rho u^2$.

BERNOULLI METHOD. Given the algebraic equation

$$x^n + a_1 x^{n-1} + \cdots + a_n = 0, \tag{1}$$

let $h_0, h_1, \ldots h_{n-1}$ be arbitrary numbers, not all zero, and form $h_n, h_{n+1}, \ldots$, by

$$h_{n+v} + a_1 h_{n+v-1} + \cdots + a_n h_v = 0.$$

If (1) has a unique root of largest modulus, then in general the quotients $h_{\mu+1}/h_\mu$ approach that root. The method can be extended to transcendental equations. Let

$$f(z) \equiv 1 + c_1 z + c_2 z^2 + \cdots \tag{2}$$

converge in some circle about the origin in the complex plane, and let

$$g(z) \equiv g_0 + g_1 z + g_2 z^2 + \cdots \tag{3}$$

represent any function analytic in the same circle, and having no zero in common with $f(z)$. Let

$$h_0 = g_0,$$

$$c_1 h_0 + h_1 = g_1,$$

$$c_2 h_0 + c_1 h_1 + h_2 = g_2$$

Then if $f(z)$ has a unique zero of smallest modulus lying within that circle, then $h_\mu/h_{\mu+1}$ approaches that zero. If there are two zeros whose

$$\begin{array}{c|cc} z^2 & h_\mu & h_{\mu+1} \\ z & h_{\mu+1} & h_{\mu+2} \\ 1 & h_{\mu+2} & h_{\mu+3} \end{array} = 0$$

moduli are less than those of all others, then the roots of approach those zeros of $f(z)$. Likewise one can form cubics whose roots approach the three smallest roots.

BERNOULLI NUMBER AND POLYNOMIAL. A Bernoulli number is a coefficient in the power series

$$\frac{x}{e^x - 1} = \sum_{n=0}^{\infty} \frac{B_n x^n}{n!}$$

The first few numbers are $B_0 = 1$; $B_1 = -\frac{1}{2}$; $B_3 = B_5 = B_7 = \cdots = 0$; $B_2 = \frac{1}{6}$; $B_4 = -\frac{1}{30}$; $B_6 = \frac{1}{42}$; $B_8 = -\frac{1}{30}$; $B_{10} = \frac{5}{66}$. Successive values of the numbers may be found from the equation $(B+1)^n = B^n$ by setting $B^k = B_k$. The numbers occur in the Euler-Maclaurin formula and in the Stirling formula.

$$\frac{t(e^{xt} - 1)}{(e^t = 1)} = \sum_{n=0}^{\infty} \frac{\phi_n(x)}{n!} t^n$$

The Bernoulli polynomial is a coefficient in the power series. The first few polynomials are $\phi_2 = x(x-1)$; $\phi_3 = x(x^2 - 3x/2 + \frac{1}{2})$; $\phi_4 = x^2(x^2 - 2x + 1)$; $\phi_5 = x(x^4 - 5x^3/2 + 5x^2/3 - \frac{1}{6})$. If the nth polynomial is expanded in a Maclaurin series, the coefficients are related to the Bernoulli numbers.

Both the numbers and the polynomials are often defined in other ways so that equations containing them should be carefully checked. They are used in numerical integration formulas and in the calculus of finite differences.

The Bernoulli who discovered these relations was Jacob (1654–1705), a member of a distinguished family of mathematicians and physicists. See also **Bernoulli Equation**; and **Logarithmic Spiral**.

BERNOULLI THEOREM. This theorem, due to James Bernoulli, was published posthumously in 1713. Let the probability of an event p be constant from trial to trial. Let the relative frequency be denoted by x/s where x is the number of successes in s trials. Let

$$P\left(\left|\frac{x}{s} - p\right|\right)$$

denote the probability of obtaining the absolute value of the deviation $x/s - p$. Bernoulli's theorem states that as the number of trials s increases, the probability of a difference in absolute value more than a stated positive amount $\in$ approaches zero. In symbols,

$$\lim_{s\to\infty} P\left(\left|\frac{x}{s} - p\right| > \in\right) = 0$$

The theorem does *not* state an ordinary proposition in the mathematics of limits:

$$\lim_{s\to\infty} \frac{x}{s} = p$$

Bernoulli's theorem is one of the "laws of large numbers." It gives precise form to intuitive feelings (about the limiting ratios of occurrences) which are not easy to formulate. See also **Aerodynamics and Aerostatics**.

BERRY. A true berry consists of a fleshy fruit, derived entirely from the ovary of a flower and its contents. Usually many seeds are embedded in the flesh. Common examples are the tomato, grape, gooseberry, and currant. Frequently, as in currants and gooseberries, the calyx tube grows around the ovary wall and forms the skin of the berry. All berries of commerce do not necessarily meet this strict botanical definition. Berries are considered an excellent source of nutrients. The principal berries of commerce are blackberry and dewberry, blueberry, cranberry, currant, gooseberry, raspberry, and strawberry. Grape and tomato are not considered commercially in the same category with berries. Several berries are described in this book. Check alphabetical index.

BERTHELOT EQUATION. A form of the equation of state, relating the pressure, volume, and temperature of a gas, and the gas constant R. The Berthelot equation is derived from the Clausius equation and is of the form

$$PV = RT\left(1 + \frac{9PT_c}{128P_cT}\left[1 - 6\frac{{T_c}^2}{T^2}\right]\right)$$

in which P is the pressure, V is the volume, T is the absolute temperature, R is the gas constant, T_c is the critical temperature, and P_c the critical pressure.

BERTHELOT, PIERRE EUGENE MARCELLIN (1827–1907). A French Chemist, Berthelot, was a professor at the Ecole Superieure de Pharmacie (1859) and at the College de France from 1865. He did important work in organic synthesis. Berthelot proved that hydrocarbons and other organic compounds could be synthesized from inorganic materials. In later years, he did valuable research in thermochemistry. Much of Berthelot's research involved dyes and explosives.

See also **Berthelot Equation**.

J. M. I.

BERTHOLLET, CLAUDE LOUIS (1748–1822). A French chemist, born in Talloires, near Annecy, France. Followed Antoine Lavoisier, but did not accept the latter's contention that oxygen is the characteristic constituent of acids. He was the first to propose chlorine as a bleaching agent. His essay on chemical physics (1803) was the first attempt to explain this subject. His speculations on stoichiometry, especially as regards relative masses of reacting atoms, profoundly affected later theories of chemical affinity.

BERTHOLLIDE COMPOUNDS. See **Chemical Composition**; and **Compound (Chemical)**.

BERYL. The mineral beryl is a silicate of beryllium (glucinium) and aluminum corresponding to the formula $Be_3Al_2Si_6O_{18}$. Crystallizing in the hexagonal system the 6-sided prisms of beryl may be very small or range up to several feet (meters) in length and 3 feet (1 meter) or so in diameter. Terminated crystals are relatively rare. Its fracture is conchoidal; hardness, 7.5–8; specific gravity, 2.6–2.9; colors, emerald green, green, blue-green, blue, yellow, red, white and colorless; luster, vitreous; transparent to translucent.

Beryl has long been used as a gem, the emeralds being a rich green variety, colored probably by minute amounts of some chromium compound. A beautiful bluish sort is called aquamarine; morganite is pink, and the golden beryl is a clear bright yellow. Other shades like honey yellow and yellowish-green are common. Metallic beryllium is obtained from beryl. Its lightness and strength make it very valuable for industrial purposes.

Beryl is found in granite rocks and especially in pegmatites, but it occurs also in mica schists in the Urals. In addition to the many European localities, including Austria, Germany, and Ireland, beryls of gem quality

are found in Africa, Madagascar (especially for morganite), and Brazil. The most famous place in the world for emeralds is at Muso, Colombia, South America, where they form a unique occurrence in limestones. Emeralds are also obtained in the Transvaal and near Mursinsk, in Siberia. In the United States, New England has furnished much beryl from its pegmatites, and for a long time the huge crystals from Acworth and Grafton, New Hampshire, were the largest known. Later, however, giant crystals even larger than those from New Hampshire were discovered in Albany, Maine, the largest of which was 18 by 4 feet (5.4 by 1.2 meters), and weighed about 36,000 pounds (16,330 kilograms). Other localities are Paris and, elsewhere, in Oxford County, Maine; Royalston, Massachusetts; North Carolina; Colorado; South Dakota; and California.

ELMER B. ROWLEY, F.M.S.A., formerly Mineral Curator, Department of Civil Engineering, Union College, Schenectady, NY

BERYLLIUM. [CAS: 7440-41-7] Chemical element symbol Be. at. no. 4, at. wt. 9.0122, periodic table group 2, mp $1287 - 1292 \pm 3\,^{\circ}C$, bp $2970 \pm 5\,^{\circ}C$. The vapor pressure at the melting point calculates to be 55 N/m^2 from the equations for the vapor pressure.

1. Solid $\log P_{(bar)} = 6.266 + 1.473 \times 10^{-4}T - 16{,}950T^{-1}$
2. Liquid $\log P_{(bar)} = 6.578 - 11{,}860T^{-1}$

Considerable variation exists in the reported specific heat data. The following appear to be representative:

TEMPERATURE °C	SPECIFIC HEAT kJ/(kg·K)
−13	1630
+25	1970
100	2130
200	2340

Similar scatter exists in the reported thermal conductivity data. An average value lies around 125 kW/(m·K).

The density of beryllium is 1.847 g/cm^3 (based upon average values of lattice parameters at 25 °C (a = 22.856 nm and c = 35.832 nm). Beryllium products generally have a density around 1.850 g/cm^3 or higher because of impurities, such as aluminum and other metals, and beryllium oxide. The crystal structure is close-packed hexagonal. The alpha-form of beryllium transforms to a body-centered cubic structure at a temperature very close to the melting point.

First ionization potential 9.32 eV; second 18.4 eV. Oxidation potentials $Be \rightarrow Be^{2+} + 2e^-$, 1.70 V; $2Be + 6OH^- \rightarrow Be_2O_3{}^{2-} + 3H_2O + 4e^-$, 2.28 V.

All naturally occurring beryllium compounds are made up of the ^9Be isotope. Artificially produced isotopes occur during some nuclear reactor operations and include ^6Be, ^7Be, ^8Be, and ^{10}Be.

The thermal neutron absorption cross section is 0.0090 barn/atom.

The electrical conductivity of beryllium is dependent upon both temperature and metal purity. It varies at room temperature between 38–42% (International Annealed Copper Standard). Electrical resistivity of 4.266×10^{-8} ohm·m at 25 °C has been reported.

Background. In 1797, Vauquelin discovered beryllium to be a constituent of the minerals beryl and emerald. Soluble compounds of the new element tasted sweet, so it was first known as glucinium from the corresponding Greek term. Quarrels over the name of the element were perpetuated by the simultaneous and independent isolations of metallic beryllium in 1828 by Wohler and Bussy. Both reduced beryllium chloride with metallic potassium in a platinum crucible. The name beryllium and symbol Be were officially recognized by the IUPAC in 1957.

Hope for the emergence of beryllium beyond the laboratory curiosity status resulted from publication of the work of the French scientist Lebeau in 1899. His paper described the electrolysis of fused sodium fluoberyllate to produce small hexagonal crystals of beryllium. Lebeau also reported the direct reduction of a beryllium oxide-copper oxide mixture with carbon to yield a beryllium-copper alloy. In 1926, Lebeau's alloy was rediscovered and found to have remarkable age-hardenable mechanical properties. A copper-beryllium alloy was first marketed in 1931, and this market remains important today.

Commercial development of beryllium in the United States was begun in 1916 by Hugh S. Cooper with the production of the first significant metallic beryllium ingot. This was followed by formation of the Brush Laboratories Company, which started its development work under the direction of Dr. C.B. Sawyer in 1921. In Germany, the Siemens-Halske Konzern began commercial development work in 1923.

Occurrence. A few years ago, when present theories concerning the formation of the universe were proposed, cosmologists suggested that only hydrogen and helium and also lithium, in very small concentrations, were present in the primordial matter. It was postulated that all other elements were produced as the result of subsequent star formation through nuclear reactions or cosmic ray radiation, thus creating all of the elements in the Periodic Table.

Studies of old stars, such as HD140283, have been made quite recently. This star is considered to be so old that it has only about 1% of the oxygen and other heavier elements that the sun has. About 1000 times more beryllium has been found than possibly could be attributed to cosmic radiation. These observations were essentially confirmed by one of the early experiments using the Hubble Space Telescope. These observations will contribute to further unraveling the remaining problems pertaining to the origin of the universe.

Occurrences of beryllium in the earth's crust are widely distributed and estimates of the amount fall in the 4–6 ppm range. Forty-five beryllium-containing minerals have been identified. Only two are commercially important — beryl, $3BeO{\cdot}Al_2O_3 \cdot 6SiO_2$, for its high beryllium content, and bertrandite, $Be_4Si_2O_7\ (OH)_2$, for its large quantities located in the United States.

In 1959, beryllium was found in the rhyolitic tuffs of Spor Mountain, Utah, containing from 0.1 to 1.0% beryllium oxide. The practical processing limit requires an average beryllium oxide content of the ore of 0.6% to compete with beryl ore processing of material with more than 10% beryllium oxide. Deposits of this processable grade are adequate for the industrial requirements of the United States for several decades at present levels of consumption. Although the ore grade is much lower than that of beryl ore, the beryllium values in the rhyolitic tuffs are acid-soluble and recoverable by established processing technology.

In pure form, beryl mineral contains nearly 14% beryllium oxide, as found in its precious forms, emerald and aquamarine. Industrial grades of the mineral contain 10–12% beryllium oxide. Beryl occurs as a minor constituent of pegmatic dikes and is mined primarily as a by-product of feldspar, spodumene, and mica operations. Only the relatively large crystals are recovered by handpicking or cobbing to supply the industrial requirements of about 4000 tons (3600 metric tons) per year. Principal suppliers have been Argentina, Brazil, China, and Russia. A mill that processes beryllium from tertrandite-bearing ores also operates in Utah, thus somewhat reducing the demand for raw beryl.

Extractive and Process Metallurgy. The production of metallic beryllium, its alloys, or its ceramic products centers around the recovery of an intermediate partially purified concentrate from ore processing. The usual intermediate is beryllium basic carbonate or hydroxide. The mill in Utah is the only one in the Western world that extracts beryllium from its ores. The processes used to extract the beryllium are based on sulfuric acid. The sulfate solutions from beryl or bertrandite sources are partially purified by solvent extraction before yielding beryllium hydroxide as the end product. The hydroxide is converted to beryllium fluoride by reaction with ammonium bifluoride. Thermal reduction with magnesium metal forms beryllium pebbles. Final purification is accomplished by vacuum melting the beryllium pebbles to remove fluorides and magnesium impurities and casting into graphite molds. Standard powder metallurgy processes are generally used to convert the cast billets to solid shapes. The prevalent final consolidation step is hot pressing.

Important Commercial Properties. Beryllium has several unique properties which have given it a position of commercial significance. Its low atomic mass, low absorption cross section, and high scattering cross section are neutronic properties of importance. These properties spurred the expansion of beryllium production beyond the pilot scale immediately after the formation of the United States Atomic Energy Commission and the initiation of nuclear reactor development programs. About 1960, structural applications using beryllium began to utilize its modulus of elasticity of 2.93×10^5 mPa, its low density, and its relatively high melting point. Beryllium has good thermal conductivity and excellent thermal capacity properties, which gave rise to its use as a thermal barrier and heat sink for re-entry vehicles and other aerospace applications. The latter properties have been coupled with favorable ductility properties at elevated temperatures for the development of aircraft brakes.

Commercial and Aerospace Applications. Although the early applications of beryllium took advantage of the element's nuclear characteristics, structural uses of beryllium in aircraft and aerospace have developed because no other known material exceeds beryllium's modulus-to-weight ratio, while still retaining significant ductility. Often, where stiffness-to-weight is a problem, engineers will turn to beryllium. Beryllium has the stiffness to contain both inertial and vibratory loads, as well as the thermal conductivity to prevent undesirable heat gradients. The density of beryllium does not penalize the payload.

Applications over the past several years have included guidance system parts, such as gimbals, gyroscopes, stable platforms, housings, mirrors, aircraft brakes, and accelerometers. In advanced (U.S.) land-based nuclear missiles, there is a precisely machined beryllium sphere, floating, warmed and protected, in a fluid bath.

This makes it possible to achieve exacting guidance without reference to external benchmarks. The beryllium sensor minutely determines all changes in acceleration and orientation and is claimed to have improved striking accuracy by some twenty times.

Applications of beryllium within the recent past have included structures that are loaded in compression. Wrought products with yield strengths approaching 690 MPa (1,000,000 psi) and 20% elongation at room temperature have been achieved.

Recent beryllium processing, such as the production of near-net shapes by way of cold and hot isostatic pressing, is reducing the cost of beryllium parts by as much as 35%. Hot isostatic processing also is being used to produce entirely new families of beryllium products, such as beryllide intermetallic compounds for rocket nozzles and other high-temperature needs, as well as metal-matrix composites for hypersonic aircraft components, and strong, lightweight aluminum alloys containing as much as 40% Be.

Researchers at the Brush-Wellman Laboratory (Elmore, Ohio) have developed a bench-scale, inert-gas atomization method for producing ultraclean, spherical powders, which then can be hot isostatic processed.

For several years, additions of Be to commercial copper- and nickel-based alloys have enabled these materials to be precipitation-hardened to strengths approaching those of heat-treated steels. Yet Cu-Be alloys retain the corrosion resistance, electrical and thermal conductivities, and spark resistance of copper-based alloys.

Very low electrical conductivity and high transparency to microwaves in microelectronic substrate applications have proven very advantageous.

Chemical Properties. Many chemical properties of beryllium resemble aluminum, and to a lesser extent, magnesium. Notable exceptions include solubility of alkali metal fluoride-beryllium fluoride complexes and the thermal stability of solutions of alkali metal beryllates.

All of the common mineral acids attack beryllium metal readily with the exception of nitric acid. It is also attacked by sodium hydroxide and potassium hydroxide, but not by ammonium hydroxide.

Beryllium interacts with most gases. Polished beryllium surfaces retain their brilliance for years on exposure to air at ambient temperatures. The oxidation rate in air increases parabolically at temperatures above 850 °C with the formation of a loosely adherent, white oxide.

Compounds of Beryllium. Ammonium beryllium carbonate solutions are prepared by dissolving the hydroxide or the basic carbonate in warm (50 °C) aqueous mixtures of NH_4HCO_3 and $(NH_4)_2CO_3$. After filtering to remove insoluble impurity hydroxides and adding a chelating agent, heating above 88 °C evolves NH_3 and CO_2 and precipitates a high-purity, basic beryllium carbonate. If the aqueous system has the stoichiometry of $(NH_4)_4Be(CO_3)_3$, analogous to the ammonium uranyl carbonate system, the basic beryllium carbonate product of hydrolysis is $2BeCO_3 \cdot Be(OH)_2$. This compound is readily dissolved in all mineral acids, making it a valuable starting material for laboratory synthesis of beryllium salts of high purity.

Beryllium hydroxide, [CAS: 133327-32-7] $Be(OH)_2$ is precipitated as an amorphous, gelatinous material by addition of ammonia or alkali to a solution of a beryllium salt at slightly basic pH values. A pure hydroxide can be prepared by pressure hydrolysis of a slurry of beryllium basic carbonate in water at 165 °C. All forms of beryllium hydroxide begin to decompose in air or water to beryllium oxide at 190 °C.

Beryllium sulfate, [CAS: 13510-49-1] $BeSO_4 \cdot 4H_2O$, is an important salt of beryllium used as an intermediate of high purity for calcination to beryllium oxide powder for ceramic applications. A saturated aqueous solution of beryllium sulfate contains 30.5% $BeSO_4$ by weight at 30 °C and 65.2% at 111 °C.

Beryllium fluoride, [CAS: 7787-49-7] BeF_2, is readily soluble in water, dissolving in its own water of hydration as $BeF_2 \cdot 2H_2O$. The compound cannot be crystallized from solution and is prepared by thermal decomposition of ammonium fluoberyllate, $(NH_4)_2BeF_4$.

Beryllium chloride, [CAS: 7787-47-5] $BeCl_2$, with a melting point of 440 °C, is used as a component of molten salt baths for electrowinning or electrorefining of the metal. The compound hydrolyzes readily with atmospheric moisture, evolving HCl, so protective atmospheres are required during processing.

Basic beryllium acetate, [CAS: 19049-40-2] $Be_4O(C_2H_3O_2)_6$, is the best known of the beryllium salts of organic acids which can be divided into normal beryllium carboxylates, $Be(RCOO)_2$, and beryllium oxide carboxylates, $Be_4O(RCOO)_6$. The basic acetate is soluble in glacial acetic acid and can readily be crystallized therefrom in very pure form. It is also soluble in chloroform and other organic solvents. It has been used as a source of pure beryllium salts.

Biology and Toxicology. Beryllium can be handled safely with reasonable controls, but it can cause serious illness if these controls are not observed. Skin and respiratory reactions can be experienced. There is, however, no ingestion problem.

The hazards are generally classified as (1) acute respiratory disease, (2) chronic pulmonary disease, and (3) dermatitis.

Dermatitis is produced by skin contact with soluble salts of beryllium, especially the fluoride. It is controlled by a program of good personal hygiene, frequent washing of the exposed parts of the body, as well as a program where clothing is laundered on the plant site.

Acute pulmonary disease is due exclusively to inhalation of soluble beryllium salts and is not caused by exposure to the oxide, the metal, or its alloys. The exact forms of beryllium causing the chronic pulmonary disease and the degree of exposure necessary to induce it are not precisely known. It is known that under the completely uncontrolled conditions existing in beryllium extraction plants before the establishment of air-count standards in 1949, when beryllium air-counts were in milligrams per cubic meter of air rather than micrograms, only about 1% of the exposed workers became ill. This would indicate a sensitivity of a limited number of individuals to beryllium.

Investigations by medical, toxicological, and engineering personnel led to the promulgation of safe limits of exposure by the Atomic Energy Commission in 1949. The disease is believed to be avoidable when air-counts are held within average limits of 2 micrograms per cubic meter of air for an 8-hour exposure, with a maximum at any time of 25 micrograms per cubic meter of air.

The Occupational Safety and Health Administration several years later issued a proposed new occupational standard for beryllium air-counts. This proposal was highly controversial.

Local exhaust ventilation is the major engineering control used to limit concentrations of airborne beryllium. Modern air cleaners allow control within recommended outplant levels of 0.01 microgram beryllium per cubic meter of air, averaged over 1-month periods.

Because of the increasing use of beryllium in a growing diversity of end products, a new study of beryllium disease was undertaken by the U.S. Department of Defense and the U.S. Department of Energy, as of December 1991. This study was precipitated by finding that nuclear-related weapons workers at Oak Ridge National Laboratory (Tennessee) were diagnosed has having chronic beryllium disease. The study will probe beryllium worker health statistics back to the mid-1980s.

BERZELIUS, J. J.1779–1848. A native of Sweden, Berzelius was one of the foremost chemists of the 19th century. He made many contributions to both fundamental and applied chemistry; coined the words *isomer* and *catalyst*; classified minerals by chemical compound. He recognized organic radicals which maintain their identity in a series of reactions; discovered selenium and thorium, and isolated silicon, titanium, and zirconium; did pioneer work with solutions of proteinaceous materials which he recognized as being different from "true" solutions.

BESSEL FUNCTION. The differential equation

$$x^2y'' + xy' + (x^2 - n^2)y = 0, n = \text{const.}$$

is called Bessel's equation of order n. Certain of its solutions (see below) are called Bessel functions. The general solution is

$$y = AJ_n(x) + BY_n(x)$$

where

$$J_n(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{\Gamma(k+1)\Gamma(k+n+1)} \left(\frac{x}{2}\right)^{n+2k}$$

and $Y_v(x) = J_{-n}(x)$ if n is not an integer. These functions are called Bessel functions of the first kind. If n is an integer, then $J_{-n}(x)(-1)^n J_n(x)$, so that $Y_n(x)$ is defined as

$$Y_n(x) = \lim_{k\to\infty} \frac{J_k(x)\cos kx - J_{-k}(x)}{\sin k\pi}$$

which is called a Bessel function of the second kind. The functions, much used in physics,

$$H_n^{(1)}(x) = J_n(x) + iY_n(x), \quad i = \sqrt{-1}$$
$$H_n^{(2)}(x) = J_n(x) - iY_n(x)$$

are Bessel functions of the third kind; they are also called Hankel functions of the first and second kind, respectively. Other combinations of Bessel functions are also given names. These functions have certain standard properties of recurrence, orthogonality, etc.

BESSELIAN STAR NUMBERS. Constants used in the reduction of a mean position of a star to an apparent position (used to account for short-term variations in the precession, nutation, aberration, and parallax).

BEST, CHARLES H. (1899–1978). Born in Maine, Best was educated at the University of Toronto, where he distinguished himself as a student of biochemistry. He collaborated with the late Dr. Frederick Banting in the isolation of the hormone insulin. He later became head of the insulin division of the Connaught Laboratories of the University as well as of the Banting and Best Research Institute. He also developed histaminase (an antiallergic enzyme) and the anticoagulant heparin.

See also **Banting, Sir Frederick Grant (1891–1941)**.

BETA BLOCKERS. See **Coronary Artery Disease(CAD)**.

BETA CENTAURI. Ranking eleventh in apparent brightness among the stars, Beta Centauri has a true brightness value of 5,000 as compared with unity for the sun. Beta Centauri is a blue-white, spectral type B star and is located in the constellation Centaurus south of the ecliptic. Estimated distance from the earth is 300 light years. See also **Alpha Centauri**; **Constellations**; and **Star**.

BETA CRUCIS. Ranking nineteenth in apparent brightness among the stars, Beta Crucis has a true brightness value of 6,000 as compared with unity for the sun. Beta Crucis is a blue-white, spectral type B star and is located in the constellation Crux (Southern Cross) south of the ecliptic. Estimated distance from the earth is 500 light years. See also **Constellations**.

BETA DECAY. The process that occurs when beta particles are emitted by radioactive nuclei. The name *beta particle* or beta radiation was applied in the early years of radioactivity investigations, before it was fully understood what beta particles are. It is known now, of course, that beta particles are electrons. When a radioactive nuclide undergoes beta decay its atomic number Z changes by $+1$ or -1, but its mass number A is unchanged. When the atomic number is increased by 1, negative beta particle (negatron) emission occurs; and when the atomic number is decreased by 1, there is positive beta particle (positron) emission or orbital electron capture.

Because atomic nuclei contain only protons and neutrons, beta particles must be created at the moment of emission, just as photons are created at the time of emission of electromagnetic radiation. Because of this creation process, the amount of energy equal to the rest energy, m_ec^2 of an electron, must be consumed when beta decay occurs. Any remaining energy can be given to the beta particle as kinetic energy. The nuclear transitions producing beta decay are between discrete energy states differing by a definite amount of energy W_0, so we expect the total energy of a beta-decay transition to be W_0. However, emitted beta particles are experimentally found to have a continuous range of total (rest plus kinetic) energies W of such magnitude that $m_ec^2 < W < W_0$, rather than all having a single energy W_0. This distribution as a function of energy (or momentum) forms what is known as a beta-ray spectrum. The shape of the spectrum depends on the sign of the charge on the beta particle (positive or negative), the energy W_0, and the degree to which the transition is forbidden (explained below). Unless energy and momentum are not conserved in the process, the energy not carried away by the beta particle must be given to some other particle. Furthermore, since the beta particle has a spin quantum number $\frac{1}{2}$, angular momentum cannot be conserved unless another $\frac{1}{2}$ unit of angular momentum can be disposed of. Both of these possible discrepancies in the conservation laws have been taken care of in the Fermi theory of beta decay through postulation of a massless particle, a neutrino or an antineutrino, which has a spin quantum number $\frac{1}{2}$ and also carries away the remaining energy and momentum. Neutrinos were difficult to find experimentally but, even before they were experimentally detected, so much evidence had been developed to show their existence that the Fermi theory of beta decay was generally accepted.

Beta-decay processes are classified as allowed or forbidden but, as in many other physical processes, the term forbidden does not mean nonoccurrence, just a significant retardation relative to the rate for allowed transitions. The degree of forbiddenness is determined by the magnitude of the difference in angular momentum between the initial and final nuclear states as well as the parity of these states. If more than one unit of angular momentum must be carried away by the decay products ($\frac{1}{2}$ unit by the beta particle and $\frac{1}{2}$ unit by the neutrino or antineutrino), the transition must be forbidden. Allowed transitions give straight-line Fermi plots, as do some forbidden transitions, but some forbidden transitions have distinct shapes other than straight lines for their Fermi plots.

A negatron emitted during beta decay has its spin aligned away from the direction of its emission (its angular momentum vector is antiparallel to its momentum vector) and hence has a negative helix, but an emitted positron has positive helix. It is because of the absence of beta particles with both positive and negative helix in both types of beta-emission processes that parity is not conserved in beta decay.

See also **Particles (Subatomic)**; and **Radioactivity**.

BETA EFFECT. Denotes how fluid motion is affected by spatial changes of the Coriolis parameter, for example, due to the earth's curvature.

The term takes its name from the symbol β representing the meridional gradient of the Coriolis parameter at a fixed latitude. A linearly sloping lower boundary to fluid in a rotating system also experiences the beta effect.

See also **Coriolis Parameter**.

BETA FUNCTION. Also called Euler's first integral, the beta function is defined as

$$B(r, s) = \int_0^1 t^{r-1}(1-t)^{s-1}dt$$

and converges for r, s positive. It is related to Euler's second integral, the gamma function, by the equation

$$B(r, s) = \frac{\Gamma(r)\Gamma(s)}{\Gamma(r+s)} = B(s, r)$$

The integral from c to x, considered as a function of x, is called the *Incomplete Beta Function*.

BETALAINES. Sometimes referred to as *beetroot pigments*, the *betalaines*[1] are made up of two main groups: (1) *betacyanins*, the principal component of which is betanin, contribute 75–95% of the total red color; and (2) *betaxanthins*, the principal component of which is vulgaxanthin-I, contribute about 95% of the yellow color. Another yellow pigment, betalamic acid, derives directly from cleavage of betanin and probably is the key intermediate in the biogenesis of all betalaines.

There has been considerable interest and research activity in connection with the betalaines during the past decade or so, stemming principally from tighter restrictions, including banning, of several synthetic colorants for foods. See also **Colorants (Foods)**.

The red and golden cultivars of beetroot (*Beta vulgaris* L.) appear to be excellent sources of both red and yellow, water-soluble colorants. A factor of concern in connection with the betalaines as possible coloring agents is their earthy flavor, directly reminiscent of beet taste. The principal contributor of this flavor is a substance known as geosmin, a complex organic alcohol. Some problems encountered to date in preparing suitable red and yellow colorants from beet raw materials, in addition to the flavor, are rather poor yields and lack of stability of the extracted substances.

BETA PARTICLE (Or β Particle). Physically indistinguishable from the electron (or positron) but usually restricted to products in nuclear reactions (beta decay). The term was coined by Ernest Rutherford, who discovered that the ionizing radiation emitted by uranium consisted of "at least two distinct types ... one that is very readily absorbed ... the α radiation, and the other of a more penetrative character ... the β radiation." Kinetic energies of beta particles range from tens of thousands to millions of electron volts. Because either electrons or positrons are emitted in beta decay, the term beta particle, a relic of an era in which its identity was unknown, is falling into disuse. See also **Alpha Particle**; and **Gamma Ray**.

BETA-PLANE. The derivative of the Coriolis parameter with respect to latitude. The beta-plane approximation, useful for the study of equatorial and midlatitude flow, assumes that the Coriolis parameter varies linearly with latitude. Explicitly, the Coriolis parameter is given approximately by

$$f = f_0 + \beta y,$$

in which y is the meridional distance from some fixed latitude where the Coriolis parameter is f_0 and β (from which the beta plane gets its name) is the meridional gradient of f at that fixed latitude.

See also **Coriolis Parameter**.

BETA-RAY CHEMICAL ANALYZERS. Instrumental beta-ray absorption techniques can be used for determining H_2 in hydrocarbons and, consequently, the hydrogen-carbon ratio. The range of concentration measurements is from 0 to 100%, although the presence of sulfur and oxygen may interfere, resulting in high H_2 readings. The measurement principle is based upon the fact that H_2 has twice as many electrons per unit weight as other atoms and, accordingly, has twice the beta-ray absorbency as carbon per unit weight. Beta-ray absorbency of the sample is measured by a null-balance ion chamber to indicate readings that are proportional to (Weight of Carbon/ml) + 2X(Weight of H_2/ml). A simultaneous density reading is proportional to (Weight of Carbon/ml) + (Weight of H_2/ml). These expressions thus permit calculation, based upon empirical calibration of the absorbency scale, of (Weight of H_2/ml) and the consequent determination of weight percent or the hydrogen-carbon ratio. Determinations require about 5 minutes, although readings can be made continuously. Less than 50 milliliters of sample are required. A convenient beta-ray source is strontium-90, with a half-life of 25 years. See also **Analysis (Chemical)**.

[1] Sometimes spelled without the last *e*.

Beta-ray backscattering techniques also are applied to determine (1) the average atomic number of a sample having a fixed thickness, and (2) the thickness of coatings having fixed composition. Elements of high atomic number scatter beta rays more intensely than those of low atomic number. The beta rays from a radioactive source strike the sample. Scattered beta rays re-emitted from the same side of the sample are detected in an ion chamber, shielded from the source, to produce a small current proportional to the backscattering effect. The sample thickness must be controlled. Sample windows must be thin and of low-atomic-number material to avoid contribution to the measured effect.

BETATRONS. A betatron is a particle accelerator developed by Donald Kerst at the University of Illinois in 1940 to accelerate electrons. It differs from the cyclotron in that the acceleration of the electrons is achieved by increasing the magnetic flux through the orbit of the electrons. The electrons travel in an orbit of fixed radius, and are accelerated by the magnetic field which also keeps them in the orbit. The betatron is essentially a transformer with a doughnut shaped vacuum tube as its secondary coil. An alternating current in the primary coils accelerates electrons in the vacuum around a circular path. Figure 1 shows the structural forms and the accelerating chamber which is placed between the poles of the magnet. The iron magnetic circuit must be laminated because of the time-varying field, although aircore betatrons can also be made. The inductance represented by the coil system is usually in a resonant circuit with a large capacitor to store the energy. Some betatrons are pulsed with the capacitor's energy discharged unidirectionally through the coils as in Fig. 1(**c**) and see later Fig. 3(**b**).

Betatrons were historically employed in particle physics experiments to provide high energy beams of electrons — up to about 300 MeV. If the electron beam is directed at a metal plate, the betatron can be used as a source of energetic x-rays or gamma rays; these x-rays may be used in industrial and medical applications.

Because the mass of the electron increases at relativistic speeds, the cyclotron becomes less efficient at higher energies, placing an upper limit on its beam energy. These relativistic effects are accommodated in the next generation of accelerators, the Synchrotrons. See also **Synchrotrons**.

History

The early methods of producing high-energy electron beams for x-ray applications required generating the full voltage to give the final electron energy and then applying this voltage to a vacuum tube into which a source of electrons at the negative electrode injected the particles. Energies or voltages of one or two million electron volts were possible, but the techniques for holding such high voltages on a vacuum tube were very difficult to extend to higher voltages. At the same time the energies desired for exploring the energetic transformations within the nucleus of atoms were an order of magnitude higher, and such voltages could not be reached with the electron accelerators of the 1930s.

Higher voltages were also needed for the medical application to x-ray therapy since it was realized that there would be a buildup of secondary ionization, the "dose" responsible for biological action, below the surface of the body at a depth which increased with x-ray energy. High skin dose imposed an undesirable limit on the dose which could be delivered to the tissue to be treated deep below the skin if voltages below one million were used. Furthermore, if electrons of sufficient energy could be produced, these electrons could be used directly on deep tissue instead of using the secondary electron ionization produced by x rays. The energy loss of an electron in penetrating waterlike tissue is about 2 MeV per centimeter provided that the electron is relativistic, that is, provided its energy is well over the value of the electron's rest mass, 511 kV. Consequently a 20-MeV beam of electrons would penetrate about 10 centimeters (4 inches) and create an ionization dose along the way. Since the radiation therapist wants to deliver the dose to such depths, electron energies adjustable from 10 to 40 MeV would be desirable for either x-ray production or for direct electron beam application.

For radiographic examination of thick metal objects, such as iron castings, to discover flaws, the thickness that can be penetrated by x rays or gamma rays depends upon the atomic number of the metal's elements and on the energy of the x-ray photons. There is an optimum energy due to the decrease of Compton absorption with increasing x-ray energy and the increase of pair production with increased energy. For iron the most penetrating photon energy is around 25 MeV, and for lead it would be only about 3 MeV.

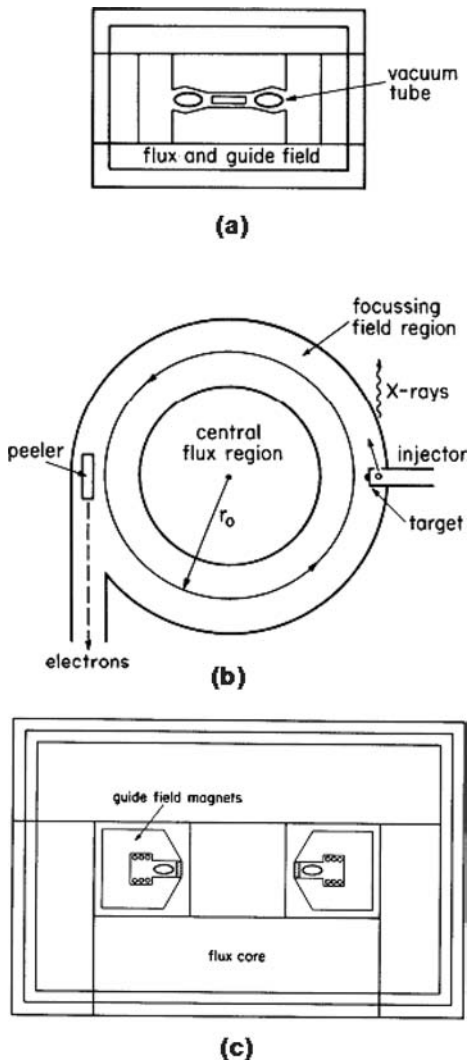

Fig. 1. (**a**) Magnet configuration of a 22-MeV betatron with the vacuum tube shown between the poles. (**b**) Toroidal vacuum tube. A resistive metallic interior coat prevents wall charge or *IR* voltage drops from deflecting the injected beam. (**c**) Configuration of unidirectionally pulsed magnets. The biased flux core links the orbit which circulates in a ring of focusing magnets.

It is evident that for the applications mentioned it would be desirable to have beams of electrons of several tens of MeV. Since the electrons would be highly relativistic at these energies, the cyclotron could not be used. The cyclotron was very well adapted to the acceleration of ions to these energies in the 10 MeV range which are far below the rest mass of the ions used. Thus the betatron method of electron acceleration, which can operate at classical and at relativistic energies, had immediate application when it was developed in 1940.

The later development of the synchrotron principle by McMillan and Veksler made possible the acceleration of electrons by radio frequency means to energies far higher than betatrons can achieve. Betatron acceleration has been applied for experiments with mesons at meson-producing energies of about 300 MeV, but the loss of electron energy by centripetal acceleration radiation can become about 10% of the final energy there, and it rises rapidly with energy. Hence the synchrotron principle of radio frequency acceleration is used to take relativistic particles to higher energies since this radiation loss is conveniently supplied by synchrotron acceleration. It is for this reason that centripetal acceleration radiation is called "synchrotron radiation," and this radiation now has found extensive applications as a light source with polarization and high intensity over a spectral range not accessible by other means.

Experiments and studies of betatron acceleration date back to times well before any of these applications. Slepian (1922), Wideröe, Walton, Breit and Tuve, and Steenbeck (late 1920s), to name a few, are among the early workers. Slepian imagined a closed iron transformer core with electrons circulating around it like the windings of the secondary coil of a transformer. The electrons were to be bent into the circulating orbit by the bending action of permanent magnets placed around the core with their magnetic field increasing with radius to provide for holding both low-energy electrons at small radii and later for more energetic accelerated electrons at a somewhat higher energy. It is interesting to note that the evolution of betatrons eventually led to just such a structure after alternating-gradient focusing was discovered.

The experiments of Wideröe and especially of Breit and Tuve and Walton were directed toward nuclear disintegration attempts with the beams. All of the applications mentioned were evident as possibilities for electron beams by the late 1930s when experiments guided by detailed theoretical work resulted in a small model operating at 2 MeV which produced an x-ray intensity equivalent to the gamma rays from 1 g of radium (Kerst, 1941; Kerst and Serber, 1941). Yields from betatrons have been sufficient for many practical purposes, but electrostatic repulsion between particles in the orbit limits the current which can be held by focusing forces. By injecting at higher energies, and hence at higher magnetic fields, magnetic focusing forces are increased and the space charge limit can be raised. The possibility of holding larger currents by the addition of a toroidal field has often been attempted, and it has ultimately been accomplished with the aid of alternating gradient or strong focusing.

Applications

When electron energies of several million electron volts became available from betatrons, the order of magnitude increase of energy was the right range for nuclear binding research, x-ray radiography in iron, deep tumor therapy, and electron beam therapy.

The lowest binding energies are for beryllium and deuterium in the 2-MeV region, but the threshold for photo-disintegration of most of the elements in the periodic table is from 8 and upward to carbon near 19 MeV. The photoneutron reaction is usually prevalent giving a radioactive product. However, betatrons are not as good as cyclotrons for producing abundant radioactive samples for tracers or for therapy. One of the characteristics of the radiation is that the x-ray spectrum is continuous giving very few photons at the peak electron energy Fig. 2. Although disintegration thresholds can be determined because the electron energy can be very accurately adjusted, the yield rises slowly with energy due to the few photons at the high-energy end of the spectrum. It requires a great effort to detect the true threshold to the precision achievable in the electron's energy. A pulse of extra flux is supplied within the orbit when the field at the orbit or the flux within the orbit reaches that for a precise energy. This expands the orbit radius at the desired energy and all the electrons are brought to the same target radius, and therefore the same energy, where a spectrum with the same high-energy limit is produced.

A fruitful use of the electron beam extracted through a magnetic channel is for the tagging of photons which subsequently produce a nuclear reaction. This is done by capturing, in an energy analyzer, the electron which has produced the photon that caused an observed coincident event. The photon energy is then the precisely known original energy of the electron minus its analyzed energy. The system is sometimes called a photon monochromator because only a very small section of the photon spectrum is used.

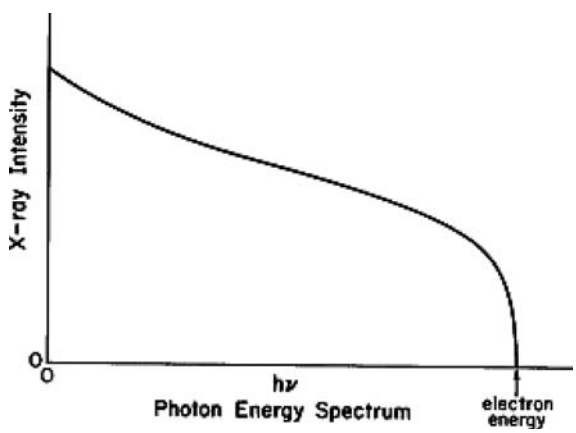

Fig. 2. Thin target photon intensity of bremsstrahlung spectrum.

The betatrons for these studies were similar to the 20- to 25-MeV therapy or radiographic machines. It was clear that meson-producing energies could be reached without too much synchrotron radiation loss. 100 MeV was too low for making up the rest mass of the muon or the pion meson although there were some betatrons made and used for nuclear experiments in this range. 300 MeV or more was chosen for the meson-producing accelerators of the period. Several synchrotrons were made and one betatron for 320 MeV was finished in 1948 (Fig. 1). This structure had a separate biased flux core through the ring of field, or guiding, magnets. The ring of field magnets was very similar to the magnets of some synchrotrons, and its coils were connected in parallel with the core flux coil so that the equilibrium radius flux-field relation would be maintained throughout the acceleration pulse. The precision of fulfilling the flux relation, and hence the constancy of the orbit radius, depended on making the coil resistance low enough so that its resistive voltage drop was small compared to the inductive voltage on the coils. The six orbit magnets weighed 60 tons (54,431 kilograms) total and the flux magnet weighed 230 tons (208,652 kilograms). The six pulses per second wave form is shown in Fig. 3(**b**). If flux biasing is used as shown in the figure, a choke coil is needed for keeping the pulse out of the dc generator which supplies the bias winding on the closed iron core. Since the flux magnetic circuit is all iron, very few bias ampere turns are needed. An alternate choice for biasing is to bias the field coils. In this case the bias current must be much larger.

The electron synchrotrons of the day tended to yield less output than the 320-MeV betatron. They used betatron action at injection with a very small flux core which soon saturated, and with the beam captured, synchrotron acceleration by radio frequency flux took over. In fact the first test of synchrotron acceleration was performed on a small 4.5-MeV betatron made by the University of Illinois group and given to the Woolwich arsenal in Britain where Goward and Barnes were able to penetrate the resistive wall coating with a radio frequency electric field and to continue the acceleration to 8 MeV.

Much later small FFAG betatrons played a role in the development of synchrotron acceleration manipulations. The purpose was to learn how to stack successively accelerated groups of particles in a ring current of sufficient magnitude for colliding beam experiments (Terwilliger, et al.). The small betatron acted as a storage ring with beams started by betatron acceleration and then picked up by the rf cavity and brought to the stacking energy. It was necessary to determine the interference of successive group accelerations on the density of phase space in the stack. Although the stacking process could be modeled on a digital computer, the experiments provided confidence that one could carry out the required physical manipulations for synchrotron stacking and storing of beams.

Another small MURA FFAG betatron of the spiral sector type with all six sectors of the same polarity was applied to the establishment of experience with the wide variety of resonances which an alternating gradient focusing accelerator must avoid, to practice passage through the transition energy when synchrotron acceleration is employed, and to carry out the operation of producing a functioning physical structure. It accelerated only to one-third of the electron rest mass, but that was sufficient to exceed the transition energy [Haxby, et al.,Ref.]. High-energy high-intensity sector-focused cyclotrons now use this spiraling pole structure to approach the rest mass energy.

Radiography of metal structures was the first commercial use of betatrons Fig. 4. In 1943 they were installed in arsenals and at Los Alamos. The decrease of the Compton-effect absorption coefficient with photon energy is offset by the rise of electron pair production causing the most penetrating radiation to require about 25-MeV electrons Fig. 5. If necessary fifteen to twenty inches of steel can be x-rayed in fifteen minutes to an hour.

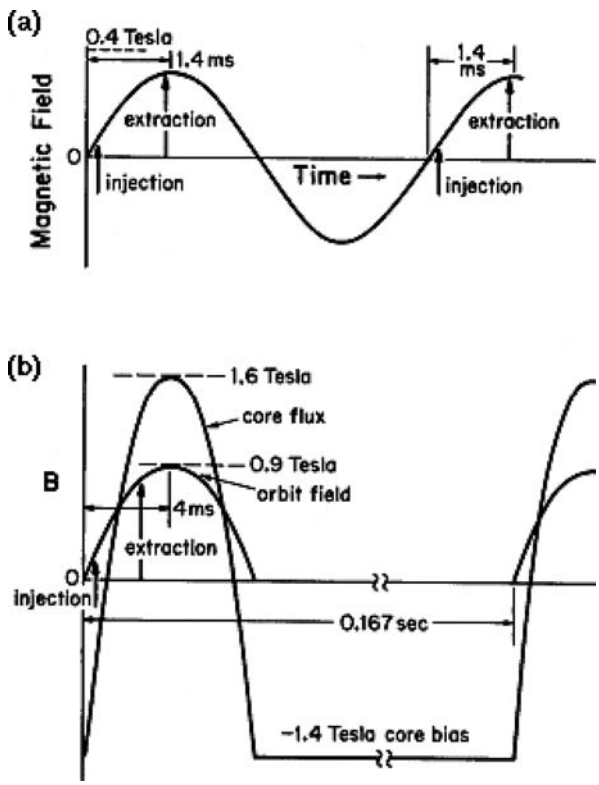

Fig. 3. (**a**) Accelerating field for sinusoidal commercial operation at 180 Hz. Three-fourths of the cycle is not used. (**b**) Six pulses per second unidirectional flux-biased wave form of the 320-MeV Illinois betatron.

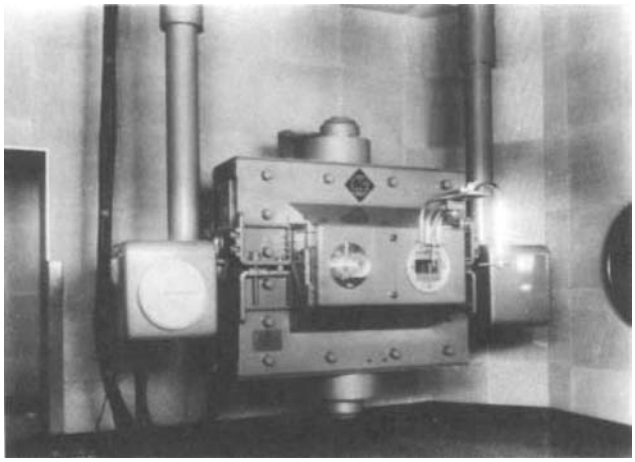

Fig. 6. Medical betatron used for deep therapy at 25 MeV.

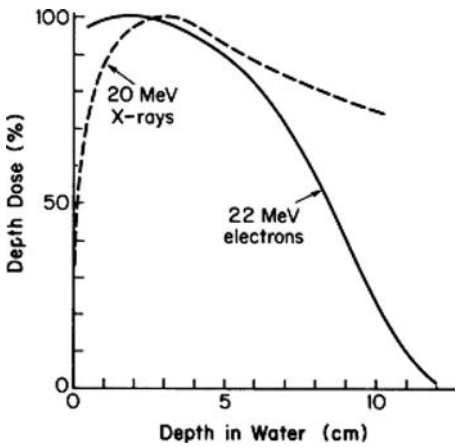

Fig. 7. Buildup of ionization below the skin for 22-MeV x rays, and range limitation of 22-MeV electrons inside the body. Depth dose curves.

As mentioned earlier the focal spot is vanishingly small because the beam naturally has small size and especially because the target can be a pointlike obstacle. A 0.002-cm platinum tip on the injector serves as a target. The high resolution possible with such a target has made betatrons especially suitable for certain high-resolution radiographic requirements.

Similar betatrons mounted differently became electron beam and x-ray beam deep therapy radiation sources (Fig. 6). Figure 7 shows how the ionization distribution in tissuelike material builds up beneath the surface for x rays from 20-MeV electrons. Since the tolerance of the patient for treatment is often limited by skin reactions at lower voltages, the minimizing of surface dose as well as the deeper penetration at voltages over 20 MeV has brought improved treatment possibilities.

A somewhat heroic effort was made to establish the physical means and techniques to adapt the order of magnitude increased radiation energy which became available in the 1940s for patient use (Quastler, et al.). Collimation, dose measurement, beam flattening, aiming, and clearing away stray electrons required new methods of solution at 20 MeV. The requirement for beam flattening results from the target radiation being predominantly within an angle of mc^2/E of the forward direction of the electrons of energy E. Lengthwise cigar-shaped absorbers are needed to reduce the central intensity thereby flattening the dose distribution in the patient. Dose measurements were aided by passage of the applied radiation directly through foils which became radioactive and integrated the dose to the patient. Ultimately betatrons were used to develop a calorimetric method which made it possible to base radiation dose at these energies on the calorie to which intermediate standards could be referred.

Treatment by the accelerated particles themselves has some advantages, and therapeutic betatrons are arranged to provide both an x-ray and an electron beam. The ionization distribution along the path of an electron beam in tissue-like material is shown in Fig. 7. At relativistic energies electrons in tissue lose about 2 MeV/cm so a 22-MeV beam as shown in the figure would go as deep as 11 cm (4.3 inches). It is evident that scattering has deflected many electrons before that depth. The finite range is advantageous because deeper tissue is not damaged. However, the multiple scattering and radiation straggling is much greater for electrons than it is for heavier particles, for example, for protons, so that a more sharply defined ionization distribution is possible with protons. It is necessary to use protons having an order of magnitude more energy to penetrate sufficiently.

BETELGEUSE *(α Orionis)*. A star whose name is a contraction of an Arabic phrase indicating that it is the "armpit of the central one," i.e., the armpit of Orion. Because of its rich reddish color, this star has frequently been referred to as the "martial one." Because it is the first star to rise of the brilliant and well-known constellation Orion, the title of "roarer" or "announcer" has been assigned to it by ancient writers.

Betelgeuse is of great interest astronomically. It is an irregular variable star. It is also one of the first stars to have its diameter measured with the stellar interferometer. The diameter is found to be variable between 12.7 and 7.8×10^8 km. At maximum diameter, the star would extend beyond the orbit of Mars, and almost to the orbit of Jupiter, if put in the sun's place.

Ranking ninth in apparent brightness among the stars, Betelgeuse has a true brightness value of 17,000 as compared with unity for the sun. Estimated distance from the earth is 500 light years. Betelgeuse is classified as a red star of special type M. See also **Constellations**.

BEUSITE. A mineral: $(Mn^{2+}, Fe^{2+}, Ca, Mg)_3(PO_4)_2$.

BEVEL GEARING. Straight-tooth and spiral-tooth bevel gearing are used to transmit motion between shafts whose axes intersect. The operation of such units is analogous to that of friction cones, which may be considered to represent the pitch cones for the bevel gearing, and which correspond to pitch cylinders for spur gearing. Straight-tooth bevel gears have teeth of involute form, but the straight-line elements converge (if extended) at the intersection of the shaft axes, in contrast to the parallel-tooth elements of spur gears. There are several forms of bevel gearing; in the most important, the gear and pinion operate at a shaft axes angle of 90°. The unit is termed miter gearing if both gear and pinion have the same number of teeth, and angular gearing if the angle between the shaft axes is less than 90°. Bevel gearing in which the shaft axes angle is greater than 90° is also used to some extent. The pitch cone angles of the pinion and gear must be complementary for a shaft axes angle of 90°.

The pitch diameter of bevel gearing is measured at the large end of the pitch cones; the addendum and dedendum are not measured in the plane of the pitch circle, as in spur gearing, but are constructed perpendicular to the elements of the pitch cone on the surface of the back cone. The tooth shape is therefore dependent upon the magnitude of the back-cone radius, rather than the pitch radius, as in spur gearing. See Fig. 1.

Mortise gears have cast-iron rims with cored slots into which hard maple cogs or teeth are fitted and held in place by wedges at the back of the rim, and are designed to operate with cast iron cast tooth pinions. Cast-tooth gearing, however, is used only where the pitch-line velocity is low and where smooth action is not particularly important.

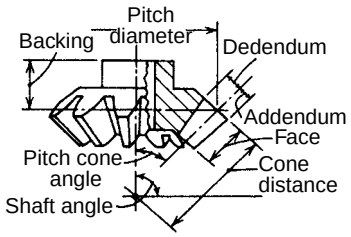

Fig. 1. Bevel gearing.

Spiral bevel gears have teeth cut in the arc of a spiral across the gear face, and bear the same relation to straight bevel gears that helical gears do to spur gears. This construction results in a larger number of teeth in contact than in straight-tooth bevel gearing, and like helical gearing, permits higher pitch-line velocities and greater load-carrying capacities for the same occupied space. They are often used to replace straight-tooth bevel gear sets.

Hypoid gearing resembles spiral bevel gearing in general appearance, but is used for transmitting power between shafts whose axes are perpendicular, but nonintersecting. They find widespread application in automobile rear-axle drives, and in numerous other instances where bevel or worm gearing is not applicable.

BEYOND EINSTEIN PROGRAM. How did the Universe begin? Does time have a beginning and an end? Does space have edges? The questions are clear and simple. They are as old as human curiosity. But the answers have always seemed beyond the reach of science, until now.

In their attempts to understand how space, time, and matter are connected, Einstein and his successors made three predictions: First, space is expanding from a Big Bang; second, space and time can tie themselves into contorted knots called "black holes" where time actually comes to a halt; third, space itself contains some kind of energy that is pulling the Universe apart.

Each of these three predictions seemed so fantastic when it was made that everyone, including Einstein himself, regarded them as unlikely. Incredibly, all three have turned out to be true. Yet Einstein's legacy is one of deep mystery, because his theories are silent on three questions raised by his fantastic predictions: (1) *What powered the Big Bang?* (2) *What happens to space, time, and matter at the edge of a black hole?* and (3) *What is the mysterious "dark" energy pulling the Universe apart?*

The answers to these questions-which lie at the crux of where our current theories fail us-will lead to a profound, new understanding of the nature of time and space. To find answers, however, we must venture beyond Einstein. The answers require new theories, such as the inflationary Universe and new insights in high-energy particle theory. Like Einstein's theories, these make fantastic predictions that seem hard to believe: unseen dimensions and entire universes beyond our own. We must find facts to confront and guide these new theories. Powerful new technologies now make this possible. And NASA and its partners are developing an armada of space-based observatories to chart the path to discovery.

Here is where the Beyond Einstein story begins. By exploring the three questions that are Einstein's legacy, we begin the next revolution in understanding our Universe. We plot our way forward using clues from observations and from new ideas connecting the worlds of the very small and the very large, from the atom out through the deepest reaches of the cosmos.

What powered the Big Bang? If the Universe is expanding, as countless observations have shown, it is only logical to assume that the Universe was more compact yesterday, even more compact the day before, and so on. At some point in the distant past, all the matter and energy we see today must have been confined to a microscopic region of unimaginably high density. This would be the moment of the Big Bang. See also **Cosmology**.

We have snapshots of the Universe as it evolved - clues to the past are all around us. In the 1960s scientists identified a pervasive microwave radiation emanating from all points in the sky. This radiation, called the cosmic microwave background, is the afterglow of the Big Bang itself. Embedded in this afterglow are slight temperature fluctuations—a little warmer here, a little cooler there-that point back to slight density differences in the infant Universe—a little more matter here, a little less there. These fluctuations are the seeds of all the structure we see today.

NASA's Cosmic Background Explorer (COBE) satellite discovered the fluctuations and, most recently, NASA's Wilkinson Microwave Anisotropy Probe (WMAP) has refined the measurement. We see how gravity has pulled these wrinkles into stars and planets. We can even determine the ratio the ratio of matter to energy, the era of first starlight, and the age of the Universe, 13.8 billion years.

What we don't know is the most basic fact: *What started it all?* Modern theoretical ideas that try to answer this question predict that the wrinkles COBE discovered arose from two kinds of primordial particles: from the energy field that powered the Big Bang; and gravitons, which are fundamental particles of space and time.

Clues to the nature of these particles exist in the Big Bang afterglow. Measurements from Beyond Einstein missions will coax information from this ancient light, which has held its secrets for so long. This would enable us to piece together the story of how time, space, and energy worked together to power the Big Bang.

What Happens at the Edge of a Black Hole? The greatest extremes of gravity in the Universe are the black holes formed at the centers of galaxies and by the collapse of stars. Gravity is so overpowering here that nothing, not even light, can escape its grasp. By definition black holes are invisible. Yet these invisible bodies disturb space considerably, offering us two ways to study them: by observing matter swirling into them and by listening to the waves of distortion they make in spacetime. See also **Black Hole**.

One key mission will create movies from the X-ray light emitted from multimillion-degree gas as it approaches a black hole's border, called the *event horizon*. Another mission will listen for gravitational waves, which are ripples in spacetime predicted by Einstein. These waves are created by black hole mergers; they move undisturbed across the "sea" of space at light speed, and offer an unobstructed view of these powerful collisions.

Einstein himself never dreamed that it would be possible to detect gravitational waves, which only distort the distance between objects as far apart as the Earth and Moon by less than the width of an atom. Yet the technology now exists to do so.

Data from X-ray satellites, such as NASA's Chandra X-ray Observatory and ESA's **XMM-Newton**, show signs of gas whizzing about black holes at close to the speed of light and hint that time is slowing as the gas plunges into the zone from which escape is impossible. Beyond Einstein missions will take a census of black holes in the Universe and give detailed pictures of what happens to space and time at the edges of these gravitational chasms. See also **Chandra X-Ray Observatory**; and **XMM-Newton (The High-Throughput X-Ray Spectroscopy Mission)**.

What is Dark Energy? The landmark discovery of the 1990s was that the expansion of the Universe is accelerating. The greatest mystery in astronomy today is the nature of this force that opposes gravity, which we call "dark energy."

Because Einstein originally thought the Universe was static, he conjectured that even the emptiest possible space, devoid of matter and radiation, might still have an energy countering gravity, which he called a "Cosmological Constant." When Edwin Hubble discovered the expansion of the Universe, Einstein rejected his own idea, calling it his greatest blunder.

But the Universe is not just expanding; the expansion rate, which appears to have slowed several billion years ago, is reving up. We live in a runaway Universe, in which the most distant galaxies visible today will soon fly off forever beyond the horizon. This acceleration could be due to the concept that "empty space" is not empty. Richard Feynman and others who developed the quantum theory of matter realized that empty space is filled with "virtual" particles continually forming and destroying themselves. These particles create a negative pressure that pulls space outward. No one, however, could predict this energy's magnitude.

Independent measurements reveal that dark energy comprises about 70% of the total mass-energy budget of the Universe. We still do not know whether or how the highly accelerated expansion in the early Universe, called *inflation* and the current accelerated expansion, due to dark energy, are related. *A Beyond Einstein* mission will measure the expansion accurately enough to learn whether this energy is a constant property of empty space, as Einstein conjectured, or whether its strength varies over time, a property predicted by modern theories of the forces of nature.

Missions

NASA's *Beyond Einstein* program moves us toward answers to this new generation of mind-boggling questions. The program is a series of

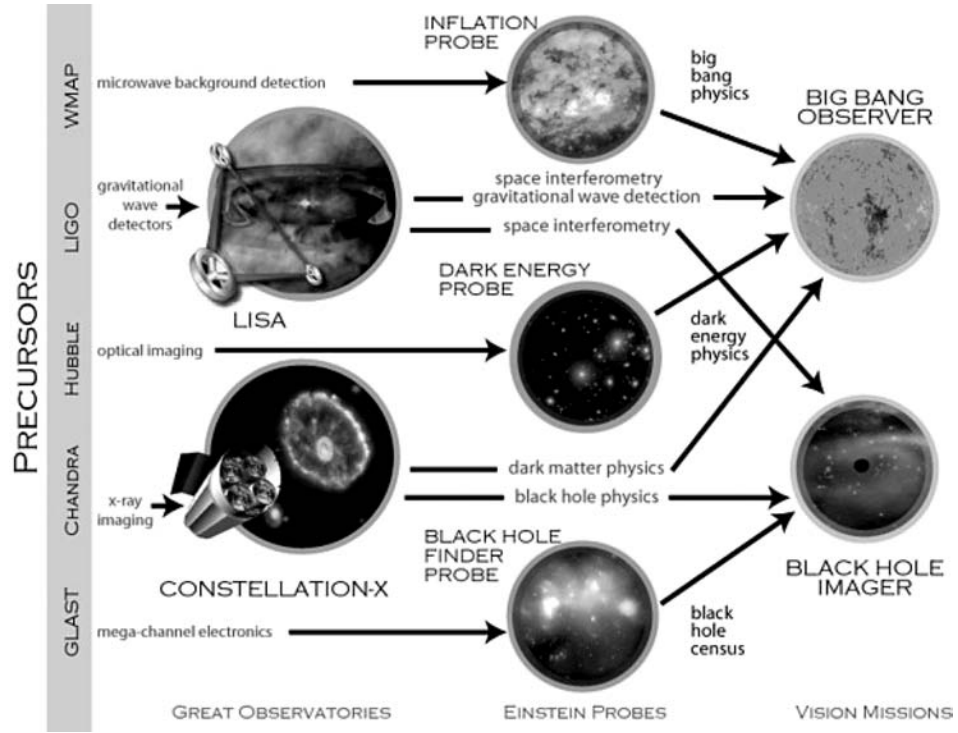

Fig. 1. *Beyond Einstein* Program. (*NASA*).

missions, large and small, that push Einstein's theories to their limits using increasingly more sensitive probes. Two great observatory missions now in development will explore extremes of space measuring X-rays and gravitational radiation; smaller missions, each aligned with one of the three questions, will follow. What we learn in these initial missions will lead us to our ultimate goal of imaging black holes and the Big Bang itself.

The *Beyond Einstein* program will build on the scientific contributions of the current generation of missions like Chandra, Hubble, and WMAP. This program will blaze new paths in the search for answers to questions about black holes, dark energy, and other outstanding issues in modern astrophysics. See Fig. 1.

The central element of the *Beyond Einstein* program is a pair of observatories currently in development: **Constellation-X** and **LISA**. A series of competitively selected **Einstein Probes** will be focused on the three central *Beyond Einstein science topics* previous discussed. These missions will go hand-in-hand with a program of technology development and theoretical studies to achieve the ultimate goal - vision missions to image a black hole and the Big Bang itself.

Great Observatories. Constellation-X and The Laser Interferometer Space Antenna (LISA) will use the complementary techniques of X-ray spectroscopy and gravitational waves to study black holes. They will probe space, time, and matter in the extreme environment near black holes and track their evolution with cosmic time. These two facilities will be a major resource for a broad astronomy and physics community. The National Academy of Sciences' decadal survey Astronomy and Astrophysics in the New Millennium developed community consensus on the most important science questions and funding priorities. It recommended both LISA and Constellation-X as high priorities for this decade.

Constellation-X will extend our capability for high resolution X-ray spectroscopy by 25 to 100 times. Its key goals are to determine the fate of gas falling into a black hole by tracking spectral features close to the event horizon, and to trace the evolution of black holes with cosmic time by obtaining detailed spectra of faint quasars at high redshift. The mission is optimized for these challenges but also provides the ability to observe other objects with unprecedented sensitivity. Constellation-X will also observe the first clusters of galaxies and be able to search for spectral features from the surfaces of neutron stars, which could finally determine the properties of matter at nuclear density.

LISA's gravitational waves offer an entirely new way to sense action in the Universe. Through them we will hear for the first time the mergers of giant black holes and the death spirals of stars they capture and swallow. Using these, we will map the knotted structure of space and time around a black hole and determine if the astonishing predictions of Einstein's theory are correct: the freezing of time and dragging of space around a black hole. LISA will also make the first complete map of merging binary stars in our Galaxy, future supernovae which could affect life on Earth. It will set important limits on background radiation from the early Universe and from catastrophic events, such as phase transitions in the vacuum or changes in the dimensionality of the Universe. See also **Laser Interferometer Space Antenna (LISA)**.

Both Constellation-X and LISA are critical to the goals of the *Beyond Einstein* program. One of these great observatories will begin development at the beginning of the program, and the other will begin development approximately three years later. NASA will determine the order based on science priority, technological readiness, and programmatic considerations.

Constellation-X Technology. Constellation-X will provide X-ray spectral imaging of unprecedented sensitivity to determine the fate of matter as it falls into black holes, and will map hot gas and dark matter to determine how the Universe evolved large-scale structures.

Lightweight, Grazing Incidence X-ray Optics. Each of the four identical Constellation-X spacecraft will carry two sets of telescopes: (1) a spectroscopy X-ray telescope (SXT) for the low energy band up to 10 keV, and (2) three hard X-ray telescopes (HXTs) for the high energy band. Both incorporate highly nested, grazing-incidence X-ray mirror arrays, which must simultaneously meet tight angular resolution, effective area, and mass constraints. Engineering test units of both SXT and HXT mirrors are under development: glass substrates with surfaces replicated from precision mandrels for SXT and HXT, and an alternative replicated nickel shell design for HXT.

X-ray Calorimeter Arrays. Two technologies are being developed in parallel: semiconducting bolometers and voltage-biased transition-edge superconducting thermistors. Both have made substantial progress toward the required energy resolution of 2 eV. Multiple approaches to fabrication of high-quality arrays and multiplexed readout amplifiers are under development.

Long-lived 50mK Coolers. Constellation-X requires reliable long-life first stage coolers operating at 5-10 K. The Advanced Cryocooler Technology Development Program (ACTDP) is already pursuing this goal through study-phase contracts, leading to completion of two demonstration coolers in 2005. The ultimate detector temperature of 50 mK will be reached by one of several adiabatic demagnetization refrigerator technologies currently under study.

Grazing Incidence Reflection Gratings. Reflection gratings dispersed onto CCDs provide imaging spectroscopy in the 0.2-1.5 keV energy range and are similar to those flown on XMM-Newton. For Constellation-X, improvements to reduce weight and increase resolution are under study. Novel event-driven CCDs have recently been developed that provide significant improvements in performance and robustness.

Solid-state Hard X-ray Imaging Detectors. At hard X-ray energies, CdZnTe detectors provide <1.2 keV resolution and high quantum efficiency over the 6-50 keV energy range. Key requirements have been demonstrated but work is continuing on extending the response at low energies and reducing the effects of electron trapping.

See also **Constellation-X Observatory**.

LISA Technology. LISA will open a new window on the Universe by enabling the detection of gravitational radiation from a wide variety of astronomical systems. It consists of a triangle of reference masses in solar orbit connected by a precision metrology system. The measurement of the relative motion of these drag-free masses allows us to sense the passage of gravitational waves through the Solar System. To use the capture of compact objects to map spacetime outside of supermassive black holes sets the sensitivity requirements at wave frequencies of 10^{-2} to 10^{-3} Hz. To measure the properties of merging pairs of supermassive black holes requires good sensitivity down at least to 10^{-4} Hz.

The key technologies are those to (1) minimize external disturbances of the reference masses, and (2) precisely measure their separation.

Disturbance Reduction System. Micronewton thrusters keep the spacecraft precisely centered about the masses. Several types which meet LISA's noise requirements have been demonstrated, and lifetime and space testing are planned. Correction signals are sent to the thrusters by gravitational reference units (GRUs), which also serve as the reference mirrors for the laser measurement system. Improvements in existing GRUs (such as those flying on the NASA/German GRACE mission) that will extend LISA's sensitivity below 10^{-3} Hz are under development.

Laser Measurement System. LISA's sensitivity above 10^{-3} Hz is set by the laser power and the measurement system. Changes in the 5 x 10^6 km test mass spacing must be measured to 10^{-12} m, or 10^{-5} fringes. That requirement can be met by existing lasers and detection systems. But orbital dynamics lead to changes in spacecraft spacing that can create a fringe rate as large as 15 MHz. This imposes stringent requirements on laser frequency stability, telescope pointing and dimensional stability, and the phase measurement system, including ultra-stable oscillators.

System Verification. A validation flight is planned on the ESA SMART-2 spacecraft, with US participation through the New Millennium mission ST-7. This program will be an important validation of the critical disturbance reduction system components, the gravitational reference units, micronewton thrusters, and the laser interferometer to measure test mass spacing.

The Einstein Probes. Complementing the facility-class Einstein Great Observatories will be three sharply focused missions, each addressing a specific science question. These missions will all be selected through an open competition.

The Joint Dark Energy Mission (JDEM). "What is the mysterious energy pulling the Universe apart?" Less than a decade ago, we did not know of the existence of an energy that is causing the expansion of the Universe to accelerate. This "dark energy" comprises approximately 70% of the mass-energy budget of the Universe, but we do not know what it is. The Joint Dark Energy Mission is an interagency partnership between NASA and the Department of Energy to develop a mission that will study dark energy and determine how it evolves with time.

The Dark Energy Probe will be designed to perform measurements of the geometry of the Universe in the redshift range z = 0.7- 1.7, where the effects of dark energy are expected to leave their most prominent signature. A particularly promising approach (and the one emphasized in the NAS CPU report) is to obtain a large sample of Type 1a supernovae to redshifts of at least z = 1.5. A mission capable of such observations requires a wide field of view telescope with about a 2-meter diameter mirror, diffraction limited down to 1 micron, and large arrays of optical and infrared imaging detectors. All of these elements require substantial technology development. The primary mirror must have much lower cost and mass-per-unit-area and be developed faster than the HST primary. The very large detector arrays are a serious challenge: they require of order a billion pixels. At optical wavelengths, silicon-based CCDs are the obvious candidates, but the requirements exceed the capabilities of current devices. At infrared wavelengths, the gap between requirements and current devices is even larger.

Several ideas for such "Dark Energy Probes" have been proposed and three of these concepts were recently selected for further study:

- *ADEPT (Advanced Dark Energy Physics Telescope).* JHU is the lead institution, and Dr. Charles Bennett is the Principal Investigator. http://www.jhu.edu/newsinfo/news/home06/aug06/adept.html
- *Destiny (Dark Energy Space Telescope).* NOAO is the lead institution, and Dr. Tod Lauer is the Principal Investigator. http://www.noao.edu/outreach/press/pr06/pr0610.html
- *SNAP (SuperNova / Acceleration Probe).* LBNL is the lead institution, and Dr. Saul Perlmutter is the Principal Investigator. http://www.lbl.gov/Science-Articles/Archive/Phys-SNAP-NASA.html

Inflation Probe. "How did the Universe begin?" Immediately after the Big Bang, the Universe appears to have undergone a period of "inflation," when it expanded so rapidly that parts of it separated from the other parts faster than the speed of light. This rapid expansion enabled slight density differences in an incredibly dense young universe to ultimately grow into the stars, galaxies and vast voids we see today. Yet what propelled this inflation? Is it the same force that is accelerating the expansion of the Universe today? The "Einstein Inflation Probe" will investigate.

The Inflation Probe aims to detect signatures of gravitational waves (with wavelengths comparable to the size of the Universe) produced by quantum fluctuations of spacetime during inflation. It will do this by measuring the weak imprint they leave on the polarization of the cosmic microwave background.

Even for optimistic models, however, this weak polarization component is very difficult to detect. It is an order of magnitude weaker than the polarization components produced by quantum fluctuations in the inflation field. The sensitivity required is roughly 20-100 times that of the HFI focal plane detector on Planck. Achieving such a vast increase in sensitivity requires significant advances: e.g., large arrays of polarization-sensitive detectors with frequency multiplexing from 50-500 GHz. Other technical challenges include the need for cold optics at low cost and 100 mK detector operating temperatures with very stable temperature control.

Black Hole Finder Probe. "How do black holes form and grow?" Scientists have identified two main classes of black holes: smaller, stellar-sized black holes that form from the collapse of massive stars; and supermassive black holes in the core of most galaxies. The latter can contain the mass of millions to billions of suns and grow by swallowing stars and gas that venture too close. This consumption releases great amounts of energy. But there is an accounting problem: Not enough light is coming from supermassive black holes to explain their growth. There are hints that much of the growth occurs behind a shroud of dust.

The Black Hole Finder Probe will conduct a wide field survey of black holes. It is likely to operate at hard X-ray/soft gamma-ray energies, where radiation emitted from these objects can penetrate any surrounding veil of gas and dust.

Such a survey instrument would need to be sensitive over an energy range of about 10-600 keV, and to have angular resolution less than 5 arcmin. Since reflective optics provide very limited fields of view at these high energies, the telescope must use coded aperture imaging. To provide sufficient sensitivity, the detector plane must have an area of several square meters with millimeter-sized pixels to provide the required angular resolution. A CdZnTe detector array seems the most likely candidate, but there remain technical challenges. Other technology problems arise in the areas of mask fabrication and data acquisition at high trigger rates.

The Vision Missions. The technology to go far beyond Einstein is within our reach if we approach the grand goals systematically, mission building upon mission, proving and refining until we achieve the required technology. Strategic investments in hardware, software, and astrophysical theory will lead the way forward to two visions.

Big Bang Observer. To explore the beginning of time, a "Big Bang Observer" will build upon LISA to directly measure gravitational waves from the very early Universe still present today. In contrast to the Inflation Probe's measurement of frozen imprints of much longer waves on the microwave background, the Big Bang Observer will observe gravitational waves in their original form, from still earlier in the Big Bang. The Big Bang Observer would give us a direct view of the creation of spacetime, a truly profound achievement.

The ultimate goal of a Big Bang Observer is to directly observe gravitational waves with sufficient sensitivity to observe the background due to the quantum fluctuations during inflation. This must be accomplished in the face of a strong foreground of gravitational waves produced by all the binary stars and black holes in the Universe. Source-by-source removal of this foreground is practical at wave periods of 0.1-10 seconds.

To separate these foreground sources requires extraordinary sensitivity and angular resolution. One possible solution consists of four separate interferometers, each including three spacecraft separated by 50,000 km. These would be spaced in a triangle around the earth's orbit about the Sun (separations of 1.7 times the Earth-Sun distance), with two interferometers sharing one apex for independent correlation. Such a configuration imposes many technical challenges, including.

Strain Sensitivity. A significant improvement in strain sensitivity, about 10,000 times better than that of LISA is needed. This will require advances in mirror fabrication, laser power and stability, phase measurement, and instrument pointing.

Acceleration Noise. A gravitational reference sensor with acceleration noise performance 100 times lower than that planned for LISA is required. This gravitational wave frequency band will not have been previously explored. To provide scientific guidance and to reduce the risk associated with making such large technical advances in one step, it would be desirable to first fly a pathfinder mission with fewer spacecraft and more modest improvements on LISA's technology.

Black Hole Imager. To explore the end of time and the edges of space, Constellation-X will measure the spectral signatures of gas swirling into black holes, and LISA will record the tune to which stars dance around it. But there is no substitute for a direct image. A "Black Hole Imager" based on a technique known as X-ray interferometry, could take this epochal picture, revealing directly the fate of matter near a black hole.

The goal of the Black Hole Imager is to enable direct imaging of the distribution and motion of matter in the highly distorted spacetime near the event horizon of a black hole. This will require angular resolution better than 0.1 microarcsecond—a million times better than Hubble Space Telescope. An X-ray interferometer is naturally matched to this task, since accreting black holes are expected to have a high surface brightness in X-rays, and this, coupled with the short wavelength, allows an instrument of relatively modest aperture and baseline to be used.

An X-ray interferometer with 0.1 microarcsecond (mas) resolution poses technical challenges. At wavelengths near 1 nm, the required baselines are about 1 km, and focal distances must be 1,000-10,000 km to obtain reasonable detector scales. This means that separate spacecraft are needed with highly controlled formation flying. Nominal requirements are: position accuracy of a fraction of a nanometer, angles known to 0.1 mas, and optical surfaces figured to 2.5 nm.

PHIL NEWMAN, National Aeronautics and Space Administration (NASA)

BIAS CELL. A small electric cell that is capable of supplying an open-circuit voltage of $1\frac{1}{2}$ or $1\frac{3}{4}$ volts indefinitely. Also used to mean the source of bias for a tube or transistor, although different numerical values than cited may be required.

BIAS (Statistics). In the theory of statistical estimation, any effect which systematically distorts an estimate from the true value, as distinct from one which may distort it on any particular occasion but averages out to zero over a long series of estimates. If t is an estimator of a parameter θ, t is said to be biased if the expectation of t is not equal to θ, and unbiased if

$$E(t) = \theta$$

BICEPS. Any of several muscles with two heads. The principal examples are (1) the biceps femoris which, in humans, lies in the back part of the thigh and flexes the lower leg, and (2) the biceps brachii of the upper arm which flexes the lower arm.

BICHAT, MARIE-FRANÇOIS-XAVIER (1771–1802). Bichat was a French medical figure of the Revolutionary period who was a leading exponent of vitalism and a founder of histology and histopathology. See also **Histology**.

Xavier Bichat, the son of a provincial physician, showed an early interest in his father's profession and soon decided to enter it himself. After completing studies in philosophy in Lyons, he began his medical education in 1791 as an apprentice surgeon at the city's principal hospital, the Hôtel-Dieu. In May 1793 a local uprising against the Revolutionary government of France led to months of civil war in which Bichat sided with the moderate and royalist parties. Leaving Lyons in August, he was conscripted into the army as a junior surgeon. After about four months' service he was discharged and made his way to Paris, arriving in the summer of 1794.

Since the medical faculties had been dissolved by the Revolutionary government in 1793, Bichat continued his hospital training at the Hôtel-Dieu of Paris. There his talents brought him to the attention of the chief surgeon Pierre-Joseph Desault (1744–1795), who took Bichat into his household almost as an adopted son. When formal medical teaching resumed early in 1795 Desault became Professor of Clinical Surgery in the new Paris school. Bichat delivered some lectures in Desault's stead, before the latter's death in June, but he never held an official teaching position. In 1797, however, he began offering a private anatomy course in rented space near the Hôtel-Dieu. There heundertook the observations and experiments that laid the foundations for his later prodigious output.

At the beginning of 1800 Bichat published his first book, the *Treatise on Membranes*. In it he identified membranes according to their common characteristics, regardless of their location in the body. A few months later his *Physiological Researches on Life and Death* appeared, the first half of which outlined his vitalistic doctrine of the life functions while the second half experimentally studied the cessation of these functions following the death of the heart, lungs or brain. Bichat's philosophical vitalism remained influential in French medicine for over half a century, despite criticism from experimental physiologists such as François Magendie and Claude Bernard. His own experimental studies, however, were rigorously empirical, including the first description of brain death, and they provided a model for Magendie's early work. See also **Magendie, François (1783–1855)**.

In his *General Anatomy* of 1801 Bichat applied the plan of the *Treatise on Membranes* to the whole body, analyzing it into 21 "simple tissues" that exhibit the same properties wherever they are found. These tissues Bichat saw as both the locus of vitality and the locus of disease. He also began publication of his *Descriptive Anatomy*, which would complement the *General Anatomy* by describing each organ in terms of its constituent tissues. The second volume, completed by Bichat, was issued after his premature death in 1802, and three remaining volumes were finished by his students. Bichat's analysis of the body into "simple tissues," whose combinations form organs in a way analogous to chemical elements forming compounds, established the basic concepts of histology and histopathology. Although Bichat distrusted the microscope, its later application brought about the convergence of his tissue theory with cell theory to produce microscopical histology.

BICHIRS *(Osteichthyes, Cladistia).* An air-breathing fish, *Polypterus*, found in African waters, including the Nile. One of a few living representatives of a group that was once abundant and is supposed to have been an ancestor of the bony fishes. It was formerly thought that *Polypterus* belonged to the ancient and extinct paleoniscids; it probably is a link between the polypterids and the paleoniscids. Maximum size of the polypterids ranges between 2 and 3 feet (0.6 and 1 meter). They are quite slender as indicated in Fig. 1. Bichirs are consumed as food by natives in some areas, but their fine bone structure makes eating quite difficult. Of the 11 species of polypterids, ten are included under *Polypterus*. The reed fish (*Erpetoichthys*) is the remaining or eleventh species. Its body is long,

Fig. 1. Bichir (*Polypterus senegalus).*

snakelike, but with a head much like the other bichirs. It also inhabits tropical West African rivers and the Nile.

BICUSPID. A tooth with two cusps, especially the premolars of humans.

BIELIDS. Bielids or Andromedes are the names applied to a meteor shower that is observed about November 24th of each year. The radiant point of the shower is in the constellation of Andromeda.

The history of the Bielids and their connection with Biela's comet is one of the interesting chapters in the development of meteoric astronomy. Biela's comet was first discovered in 1772, but was not found to be periodic. In 1826, Biela discovered the comet again, and it now bears his name. Its orbit is elliptical, with a period of about 6 years. In 1832, the comet passed very close to the earth. In 1845, the comet was observed to break in two, and in 1852, at the time of the predicted return, it was found that the two parts of the comet were both very faint and separated by over a million miles. They were unfavorably located relative to the sun for observation in 1859, and at the time of the return in 1866 they were not to be found.

The first mention of a swarm of meteors located on the orbit of Biela's comet is found in the display of December 5, 1741, when a brilliant shower was observed in Russia. The swarm was observed during December in 1798, 1830, and 1838. By 1838, the radiant point had been calculated and located, apparently in Cassiopeia. By 1867, the date of the shower had shifted to November, and thereafter, it has always been observed in that month. Up to 1885, many brilliant meteors were associated with the radiant point, with from two to four observers on November 27th of that year observing no less than 39,546 meteors in 4 hours and 8 minutes. Since 1899, very few members of the shower have been observed, and it is evident that perturbations have shifted the orbit of the main swarm well outside the orbit of the earth. See also **Meteoroids and Meteorites**.

BIENNIAL. Many plants, including some of the commonest cultivated ones, require 2 years of growth to complete their life cycle. Such plants are called biennial. During the first year of growth, they commonly form a close rosette of leaves growing from a very short stem and spreading out close to the ground; or they form a head (as in the cabbage), and develop a thick tap root in which is accumulated a considerable amount of food reserves. During the second year of growth, this reserve food is drawn upon to permit the development of a tall stem and flowers and fruit. Beets and carrots are examples of biennial plants in which the root rich in stored food reserves becomes an important source of food for humans.

BILE. A bitter alkaline fluid secreted by the liver into the duodenum, which aids in the digestion of food. The chief components of bile are bile salts and bile pigments. Because of its strong alkalinity, bile neutralizes the acid coming into the duodenum from the stomach. The bile not only performs important functions in the process of digestion, but also serves as a vehicle for the excretion of waste products from the body.

Bile salts help in the breakdown of fat in the intestines and in fat absorption through the intestinal wall. The bile salts are injected into the digestive canal at the duodenum. They are not excreted, but are almost totally absorbed through the walls of the intestine, to be used over and over again. Bile pigments are derived from the hemoglobin of broken-down red blood cells and are excreted with the feces. When the pigments appear in excessive amounts in the blood, the mucous membranes and conjunctiva of the eye become stained a pale yellow, and the patient is said to be jaundiced.

Bile is continually secreted by the liver and stored in the gallbladder. Here the bile is concentrated by the absorption of water through the walls

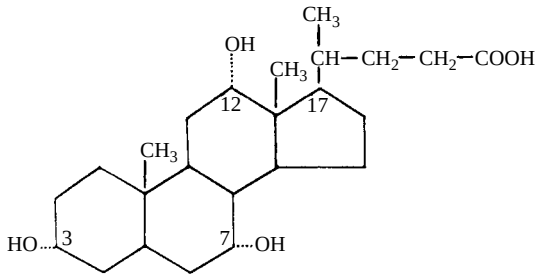

Fig. 1. Cholic Acid.

of the gallbladder. Bile is released from the gallbladder into the intestine when food passes through the pyloric valve from the stomach into the small intestine. Gallstones are formed of constituents of the bile which have settled out of solution. The stones vary in size, color, and structure, according to the materials composing them.

An inadequate supply of bile contributes to vitamin A deficiency because of disturbances of the intestinal track which prevent the effective absorption of the vitamin. In an average adult, from one-half to one liter of bile is secreted every 24 hours, the quantity depending upon the amount and kind of food eaten. The absence or lack of secretion of bile is known as *acholia*.

Part of the cholesterol newly synthesized in the liver is excreted into bile in a free non-esterified state (in constant amount). Cholesterol in bile is normally complexed with bile salts to form soluble cholic acids, Free cholesterol is not readily soluble and with bile stasis or decreased bile salt concentration may precipitate as gallstones. Most common gallstones are built of alternating layers of cholesterol and calcium bilirubin and consist mainly (80–90%) of cholesterol. Normally, 80% of hepatic cholesterol arising from blood or lymph is metabolized to cholic acids and is eventually excreted into the bile in the form of bile salts.

The C_{24} bile acids arise from cholesterol in the liver after saturation of the steroid nucleus and reduction in length of the side chain to a 5-carbon acid; they may differ in the number of hydroxyl groups on the sterol nucleus. The four acids isolated from human bile include *cholic acid* (3,7,12-trihydroxy), as shown in Fig. 1; *deoxycholic acid* (2,12-dihydroxy); *chenodeoxycholic acid* (3,7-dihydroxy); and *lithocholic acid* (3-hydroxy). The bile acids are not excreted into the bile as such, but are conjugated through the C_{24} carboxylic acid with glycine or taurine, $NH_2-CH_2-CH_2-SO_3H$. This esterification of the bile acids to soluble conjugates occurs in the microsomes and requires coenzyme A, magnesium ion, and ATP (adenosine triphosphate). Although taurocholic acid predominates at birth, the most abundant of the bile acids in the adult is glycocholic acid. In alkaline bile, the conjugated bile acids exist in their ionized form as the bile salts, glycocholate or taurocholate. Bile salts can function as effective product feedback inhibitors of hepatic cholesterol synthesis. Because of their detergent action, bile salts play an important role in the absorption of cholesterol, fats, and fat-soluble vitamins. The bile salts are believed to facilitate absorption of these compounds by the formation of micelles or aggregates of low osmotic pressure. The bile salts themselves are not absorbed during this process. Their absorption from the intestine occurs at a different site and at an entirely different rate from that of the lipids. Approximately 95% of the bile salts are reabsorbed, enter the enterohepatic circulation, and are ultimately re-excreted into the bile for further utilization in lipid absorption.

Most of the hormones that are normally conjugated in the liver to form glucuronides or sulfates, such as the steroids, thyroxine, epinephrine, and norepinephrine, are secreted into the bile, but to a varying degree, may be re-absorbed in the intestine and eventually excreted in the urine. The 17-hydroxysteroids, including cortisol, are secreted into the bile primarily as reduced glycuronide conjugates. More than 70% of these conjugates enter the enterohepatic circulation and are eventually excreted into the urine; less than 30% are found in the feces. Progesterone, after its conversion to pregnanediol, is also excreted into the bile primarily as the glucuronide, some 75% of which is eventually excreted in the feces. Most androgens are excreted as sulfates in the urine, part of which are of nonhepatic or nonbiliary origin. Significant amounts of estrogens are excreted into bile as estriol glucuronide or estrone sulfates. Many derivatives of epinephrine and norepinephrine are eventually conjugated with either glucuronide or sulfate at the 4-hydroxy position and excreted into the bile. Thyroxine is predominantly conjugated with glucuronic acid and is excreted as such

into the bile. The bile, however, is not a significant route for the net disposal of thyroxine, since this hormone is rapidly reabsorbed, enters the enterohepatic circulation and is eventually excreted as urinary metabolites.

The major components of bile, the bile pigments, can account for 15–20% of the total solids. *Bilirubin* comes primarily from the degradation of heme in the reticuloendothelial system in the spleen, bone marrow, and to a lesser extent, the liver. The initial step in the metabolism of heme is the cleavage of the porphyrin ring and elimination of the alpha methylene carbon to produce an open tetrapyrrole. This may exist as a complex with iron and globin called choleglobin. After removal of the iron and globin, the resulting tetrapyrrole, biliverdin, is rapidly reduced to bilirubin, the major pigment in human bile. Not all bilirubin results from the breakdown of hemoglobin from mature red cells. The early appearance of labeled bilirubin after injection of precursor glycine-^{14}C indicates that some bilirubin (approximately 10%) may arise from: (1) the rapid breakdown of immature red cells in the bone marrow; (2) from heme that had not entered hemoglobin; or (3) from the destruction of newly formed red cells in the peripheral circulation. This "shunt" pathway for bilirubin formation may predominate in pernicious anemia and some porphyrias. A small amount of bilirubin may also arise from other heme pigments, such as myoglobin or the cytochromes. The bilirubin that enters the blood is rapidly and solely bound to albumin. Normal circulating levels of bilirubin are less than 1 mg/100 ml. Free bilirubin, which readily crosses the blood-brain barrier in the newborn, and to a lesser extent in the adult, is an effective uncoupler of oxidative phosphorylation in the brain and is highly toxic.

The hepatic transport of bilirubin from plasma to bile involves three independent, but related mechanisms, i.e., uptake, conjugation, and secretion. Plasma bilirubin is dissociated from plasma albumin in the liver and is rapidly concentrated in the cytoplasm of the hepatic cells by an unknown mechanism which precedes and is relatively independent of any subsequent hepatic conjugation. After concentration in the liver, bilirubin is conjugated with 2 moles of glucuronic acid to form bilirubin diglucuronide, the glucuronic acid moieties being attached in ester linkage to the carboxyl groups on the propionic acid side chains. See Figs. 2 and 3.

Glucuronyl transferase, the enzyme catalyzing the final step, is located in the smooth endoplasmic reticulum of liver and to a lesser extent in kidney and gastric mucosa, where a small amount of extrahepatic conjugation may occur. This enzyme has not been purified and it is unclear whether it nonspecifically catalyzes glucuronide conjugation of many non-bilirubinoid substrates, or is bilirubin specific and a member of a large group of closely related glucuronyl transferases. Its activity can be induced by a variety of drugs and can be inhibited with steroids or steroid glucuronides found in plasma of pregnant women.

Crigler-Najjar's disease in humans is characterized by increased levels of unconjugated bilirubin in the serum. A genetic impairment of glucuronyl transferase, the enzyme responsible for the transfer of glucuronic acid from uridine diphosphate glucuronic acid, exists not only in the liver, but in the kidney as well. Gilbert's disease is characterized by a mild increase of unconjugated bilirubin in the plasma, which may result from a partial impairment of glucuronyl transferase, from a defect in bilirubin transport in the blood, or a defect in hepatic uptake. In subjects with Dubin-Sprinz or Dubin-Johnson disease, the serum contains high levels of both unconjugated and conjugated bilirubin, and an unidentified brown pigment is present in the liver. A defect in the secretion of the bilirubin conjugates from the hepatic cell is a probable causative factor. Rotor's disease is also characterized by increased serum levels of both unconjugated and conjugated bilirubin, but it differs from Dubin-Sprinz disease in that the hepatic brown pigment is not found. The foregoing syndromes are sometimes collectively referred to as *idiopathic hyperbilirubinemia*.

The mild nonhemolytic jaundice often present in the newborn (physiological jaundice) or the more severe jaundice and kernicterus in premature infants may result in part from an inability of the immature liver to conjugate bilirubin; low hepatic levels of both glucuronyl transferase and uridine diphosphate glucuronic acid dehydrogenase (the enzyme that catalyzes the synthesis of uridine diphosphate glucose glucuronic acid from uridine diphosphate glucose) are found in fetus and newborn. Hepatic secretion of conjugated bilirubin may also be impaired.

BILLFISHES *(Osteichthyes)*. Of the family *Istiophoridae*, there are approximately ten species characterized by bills of rounded cross section and two ridges (on each side of caudal peduncle) immediately in front of the tail. It should be noted, as mentioned later, that the bill of the swordfish is flattened and there is but a single ridge on the caudal peduncle. In the overall family of billfishes are the sailfishes, spearfishes, and marlins. Members of this family are fish eaters. The bill is used in club-like fashion to stun their victims, such as a school of frigate mackerel, as they speed through such a group.

Sailfish. Because the dorsal fin is long and exceptionally high, resembling a sail as shown in Fig. 1, the sailfish is the most easily recognized of the istiophorids. The upper jaw of the sailfish is prolonged into a sharp sword resembling that of the related swordfish. The Pacific sailfish (*Istiophorus orientalis*) constitutes the largest species — up about 220 pounds (100 kilograms), and 11 feet (3.4 meters) in length. Somewhat smaller, the Atlantic *I. albicans* runs about the same length, but with a maximum weight of only about 125 pounds (57 kilograms).

Marlin. The black marlin of the Indo-Pacific is probably the easiest of the marlins to identify. A specimen of this fish (*Istiompax marlina*)

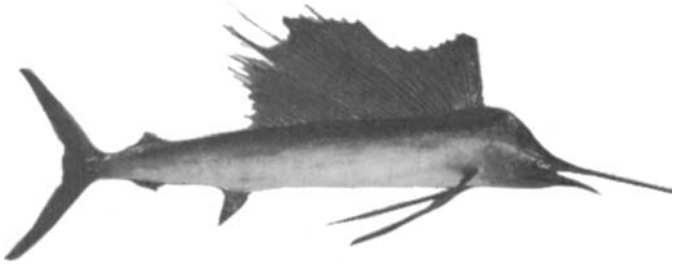

Fig. 1. Sailfish.

has been recorded at 1560 pounds (708 kilograms) and a length of $14\frac{1}{2}$ feet (4.4 meters), caught off Peru (Cabo Blanco). The Pacific striped marlin (*Makaira audax*) features ten or more vertical stripes on its sides. Maximum weight is about 600 pounds (272 kilograms). The Pacific blue marlin (*M. ampla*) also has vertical stripes. The blue marlin has a maximum weight of about 1400 pounds (635 kilograms). Blue marlins are also found in the Atlantic, normally no farther north than Long Island. They are quite similar to their Pacific counterparts. Also well known among sportsmen is the Atlantic white marlin (*M. albida*), with a maximum weight just in excess of 100 pounds (45.4 kilograms) and a length approaching 9 feet (2.7 meters).

Swordfish. Of the suborder *Scombroidei* (mackerels) and family *Xiphiidae*, the swordfish (*Siphias gladias* Linne) has an elongated, tunalike body, lacking scales. Only juveniles have small, highly degenerate scales. The skin, however, has a rough texture, since it is covered by dermal teeth somewhat like those in sharks. The most distinctive feature of the species is the "sword," a long dagger-shaped beak, which in adults can comprise one third of the entire length of the fish. It is formed from elongation of the upper jaw, intermaxillary, ethmoid, and vomer bones. The lower jaw is only slightly elongated. The family is represented by the sole genus and species given above. The fish attains a length of over 13 feet (4 meters) and a weight of over 660 pounds (300 kilograms). The fish is widely distributed in tropical and temperate parts of every ocean. It is also found in the Mediterranean and occasionally in the Black Sea. It occurs along Europe's Atlantic coast as far north as southern Norway, but swordfish rarely penetrate the North Sea, Scandinavian waters, and the Baltic Sea. Its back is blue-black; the sides are gray-blue, and the belly is white.

Swordfish spawning sites are located in the southern part of the Sargasso Sea and, to a lesser extent, in the Mediterranean. The swordfish is popular wherever it occurs because of its flavorful meat, but is of major significance mainly in Japan. Sports fishermen along the Atlantic and Pacific coasts of the United States catch swordfish with hooks and harpoons. One of the kings of the sea, the swordfish puts up a mighty fight, which it often wins. Swordfish caught off the Hawaiian Islands are sometimes marketed in the United States along with swordfish from other regions. The Hawaiian swordfish normally weighs about 220 pounds (100 kilograms). BILLOW CIRRUS CLOUDS. See **Clouds and Cloud Formation**.

BILLOW CLOUD. See **Clouds and Cloud Formation**.

BIMETAL THERMOMETER. Thermostatic bimetal can be defined as a composite material, made up of strips of two or more metals fastened together, which, because of the different expansion rates of the components, tends to change its curvature when subjected to a change in temperature.

With one end of a straight strip fixed, the other end deflects in direct proportion to the temperature change and the square of the length, and inversely as the thickness, throughout the linear portion of the deflection characteristic curve. If a strip of bimetal is wound into a helix or spiral and one end is fixed, the other end will rotate when heat is applied. The angular deflection varies directly with the temperature change and the length of the strip, and inversely with the thickness of the material, over the linear parts of the deflection characteristic curve. Bimetals show uniform deflection only over part of the deflection characteristic curve, as shown in Fig. 1. The three types of elements most commonly used in thermometers are shown in Fig. 2.

Bimetal thermometers are made in ranges from $+1000\,^{\circ}$F ($538\,^{\circ}$C) down to $-300\,^{\circ}$F ($-184\,^{\circ}$C) to and lower. However, at low temperatures, the rate

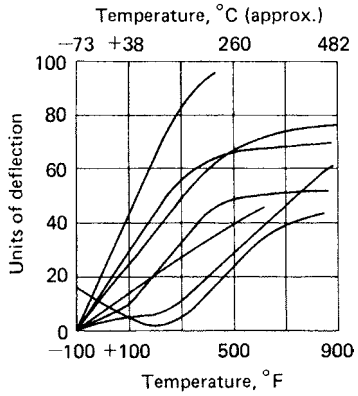

Fig. 1. Deflection characteristics of various bimetals.

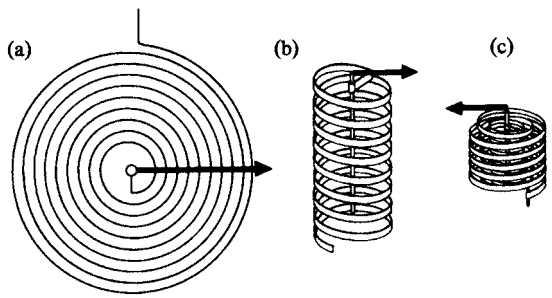

Fig. 2. Principal configurations of elements used in bimetal thermometers: **(a)** flat spiral, **(b)** single helix, **(c)** multiple helix.

of deflection drops off quite rapidly. Because of its long-term instability at high temperatures, the maximum temperature for continuous use is about $800\,^{\circ}$F ($427\,^{\circ}$C). However, special bimetal thermometers can be obtained for continuous use up to $1200\,^{\circ}$F ($649\,^{\circ}$C). Good bimetal thermometers retain their accuracy indefinitely. Usually industrial bimetal thermometers read with an accuracy of $\pm 1\%$ at any point on the scale. The speed of response of bimetal thermometers is generally about the same as that for liquid-in-glass thermometers in similar ranges.

The thermostatic bimetal approach is used widely in a variety of thermostatic-type temperature-control situations, as found in heating and air-conditioning systems and in automotive cooling systems, among others. Bimetals are also used in thermal type time-delay relays and switches.

BIMORPH CELL. Two piezoelectric plates cemented together in such a way that the application of a potential to them causes one to expand and the other to contract, thus producing a bending of the combination.

BINARY. Descriptive of a system containing two and only two components. Such a system may be a chemical compound composed of two elements, an element and a group (hydroxyl, methyl, etc.), or two groups, (e.g., oxalic acid). It may also be a two-component solution or alloy.

BINARY CLOCK. See **Clocks**.

BINARY-CODED DECIMAL (BCD). A coding system for characters using six binary digits to represent each character. The system is widely used in the computer field.

BINARY GRANITE. A granite containing only the essential minerals quartz and feldspar. Also used to describe granites which contain muscovite and biotite micas.

BINARY NUMBER. A number system that uses the number 2 as the base (radix) instead of 10 as used in the decimal system. The only digits are 0 and 1. The successive binary integers are 0, 1, 10, 11, 100, 101, 110, 111, 1,000 ... etc. The binary fractions are 0.1 ($\frac{1}{2}$), 0.01 ($\frac{1}{4}$), 0.001 ($\frac{1}{8}$) ... etc. Admittedly, the system requires many more positions to express a given number than is true of the decimal system. However, in terms of computing hardware, there are many more devices or systems which can be used to represent binary numbers than for any other base. A system with

both an "on" and an "off" state, a positive and a negative state, or a high and a low state, can be used to represent binary numbers. Binary digital computers have been constructed in which mechanical, relay, electronic, and fluidic logical elements were used — along with mechanical, relay, electronic, acoustic, magnetic, photographic, and other storage elements. Most computers that are referred to as "decimal" computers are internally coded in binary.

BINARY STARS. The term *binary star* was apparently first introduced by Sir William Herschel (1802) to designate, "a real double star — the union of 2 stars that are formed together in 1 system by the laws of attraction." Binary stars are frequently classified under three types — *visual binaries, spectroscopic binaries,* and *eclipsing binaries*. Each of these types is described in separate entries in this book. A binary system also falls within the general definition of *double star*. See also **Double Star**.

A general definition of binary star (system) describes a system of two co-orbiting stars. Not many years ago, it was believed that about 25% of all stars were binary systems, with a considerable percentage, possibly as much as 10%, being multiple systems, i.e., containing more than two stars. As pointed out by Heintz in the preface of his 1979 book (see list), "Double and multiple stars are the rule in the stellar population, and single stars the minority, as the abundance of binary systems in the space surrounding the sun shows beyond doubt." See also **Cosmology**.

Considerable astronomical research into the presence and characteristics of binary stars has gone forward since about 1830, commencing of course with rather simple instruments. During the early part of the present century, the study of binary stars was central to much astronomical research. With the development of more advanced equipment, such as electronic detectors, very large optical telescopes, and the entry of radio astronomy in the 1950s–1960s, which greatly increased the vista of astronomical investigation, researchers generally became more intensively interested in the more remote regions of space, with relatively few scientists concentrating on binary systems. However, it is interesting to note that, during recent years, the study of binary systems has regained a high degree of interest and that such studies are now one of the important keys to the investigation of stellar evolution. See **Cosmology**.

Early investigators found a direct correlation between the period of revolution of a binary star and the eccentricity of its orbit, with systems of short periods having the smaller eccentricities. They found that there is a regular gradation from pairs with short period, in which the stars are practically in contact, to pairs so widely separated that the physical connection is only indicated by their common proper motion through space. It was also learned that, in pairs whose components are of equal brightness, both stars have the same spectral type; while in systems where the brightnesses are different, the fainter star is bluer if the brighter star is a giant, and redder if the brighter star belongs to the main sequence.

Research was undertaken as regards the masses of these stars. Using data on gravitational attraction, the binary stars were the only stars (with exception of the sun) where masses could be determined. In the case of a visual binary star, after the orbit has been determined and the stellar parallax of the system obtained, the combined mass of the two stars may be obtained by a direct application of the Keplerian harmonic law. In the case of eclipsing binaries that are also spectroscopic binaries, it is possible to make a complete solution for the specifications (i.e., masses, densities, sizes, luminosities, and approximate shapes) of both members of the system.

The evolution of stars in such systems depends critically on two parameters: the ratio of the stellar masses and their period of revolution. The combined effect of these quantities is due to the differences in the gravitational attraction among the component stars. The lifetime of a star depends on its mass, being longer for low mass stars. If the two components are wide enough, that is, if the maximum radius that either star reaches is always considerably less than the separation of each from the center of gravity, then the stars will evolve as if in isolation. They will keep all of their mass (neglecting the effects of stellar wind-driven mass loss) and appear as a "two star cluster." As the separation is decreased between the centers, the tidal interaction of the stars increases. If the two are close enough (and for most mass ratios, this means periods shorter than several weeks), then, at some stage in the evolution of one of the components, its radius may exceed the critical distance, called the *Roche limit*, at which the tidal attraction from the companion dominates over the central gravity from the evolving star. The outer layers are less bound to their parent star and flow, in winds and streams, toward the companion. Considerable mass and angular momentum is lost from the parent star to the companion, and much is also carried away from the system. This is the dominant effect that drives the subsequent evolution of the pair, and differs among systems for reasons which are highly individual and not yet clear.

What is clear is that in some systems, the mass ratio can be reversed, making the mass losing star the less massive of the two. This was first recognized as the so-called Algol Paradox, named after the first system so studied, in which the more evolved (giant) member of the binary is by far the less massive of the two. Stars which are filling this critical volume are called either *contact* if the two stars are embedded in a common envelope, like the W Ursa Majoris stars, or *semi-detached*, like β Lyrae and Algol, when only one star is the critical size. This star need not be the most evolved of the pair, however. In low mass systems, which have evolved to the point of having a compact white dwarf or neutron star companion, the star which is losing mass may be the more massive of the two and still on the main sequence. These are the progenitor systems for novae, like DQ Herculis and RS Ophiuchi, and cataclysmic variables like SS Cygni and U Geminorum and the AM Herculis stars. X-ray emission accompanies the accretion of material onto a degenerate object from a fairly low mass (solar mass range) primary, like Herculis X-1 and Centaurus X-3, or black hole, like LMC X-3, and most x-ray binaries are of this type. A notable exception is the class of high mass systems, like Cygnus X-1, in which the primary is an evolved massive star and the accreter may be a black hole or neutron star sitting in the enhanced stellar wind from the companion.

The binary pulsars and millisecond pulsars, are recently discovered systems which appear to be remnants of close binary systems. In the millisecond group, which are weakly magnetic pulsars with rotation periods of the order of a few milliseconds, the binary appears to have disrupted while the binary pulsars are widely separated stable systems. The prototype of the latter group, PSR 1913 + 16, has shown orbital changes consistent with the emission of gravitational radiation predicted by general relativity and is one of the most important tests of that theory.

Systems which have not reversed their mass ratio and which are detached but still tidally coupled often show enhanced levels of magnetically generated activity. These are the RS Canes Venaticorum stars, which have periods ranging from about 0.5 to 40 days, depending on the evolutionary state of the primary, in which active chromospheres have been observed on one or both of the pair. Algol systems can also show this kind of activity.

BINARY STATE. This term is applied to the property of a Boolean variable, i.e., it can assume either of two mutually exclusive alternatives called binary states. In engineering practice, the symbols 1 and 0 are assigned to the two possible values of the Boolean variable. Usually, 1 represents "Yes," "On," or "True." Similarly, 0 represents "No," "Off," or "False." In digital computer logical circuits, these two states are represented by discrete current or voltage levels.

BINDING ENERGY. This term is used in atomic physics with two closely related meanings: the binding energy of a particle (or other entity) is the energy required to remove the particle from the system to which it belongs; the binding energy of a system is the energy required to disperse the system into its constituent entities. Explicit definitions are obviously necessary.

Some explicit definitions for the binding energies of particles are the following:

(1) The *electron binding energy* is the energy necessary to remove an electron from an atom. It is identical with the ionization potential.

(1a) The *total electron binding energy* is the energy necessary to remove all the electrons from an atom to infinite distances, so that only the nucleus remains. It is equal to the sum of the successive ionization potentials of that atom.

(2) The *proton binding energy* is the energy necessary to remove a single proton from a nucleus. Most known proton binding energies are in the range 5–12 MeV, although that for ^{2}H is 2.23 MeV, that for ^{4}He is 19.81 MeV, and those for ^{5}Li and ^{9}Be are negligible.

(3) The *neutron binding energy* is the energy required to remove a single neutron from a nucleus. Most known neutron binding energies are in the ranges 5–8 MeV, though that for ^{2}H is 2.23 MeV, that for ^{9}Be is 1.67 MeV, and that for ^{12}C is 18.7 MeV.

(4) The *alpha-particle binding energy* is the energy required to remove an alpha-particle from a nucleus. For most light nuclides the alpha-particle binding energy is positive and is equal to several MeV. For nuclides of mass number about 125, it is approximately zero. For nuclides of mass number about 150 to 200, it is negative by about 1 to 3 MeV, but the magnitude of the Coulomb potential barrier at the nucleus is sufficiently large that penetration by an alpha particle is so improbable that lifetimes for alpha disintegration are generally too long for detection of alpha activity. For most nuclides of mass number exceeding 200, the alpha-particle binding energy is negative by about 4 to 8 MeV, which is a negative binding energy of sufficiently large magnitude to give a measurable probability of penetration of the potential barrier by an alpha particle, hence an observable alpha activity.

Some explicit definitions for the binding energies of systems are:

(1) The *nuclear binding energy* is the energy that would be necessary to separate an atom of atomic number Z and mass number A into Z hydrogen atoms and $A-Z$ neutrons. This energy is the energy equivalent of the difference between the sum of the masses of the product hydrogen atoms and neutrons, and the mass of the atom; it includes the effect of electronic binding. (See *total electron binding energy* above.)

(2) The binding energy of a solid is the energy required to disperse a solid into its constituent atoms, against the forces of cohesion. In the case of ionic crystals, it is given by the Born-Mayer equation. See **Crystal**.

Although the concept of the atom has not been in serious question for nearly a half-century, full understanding of the forces that hold the neutrons and protons together has not yet been achieved. In 1927, Aston found that experimentally measured isotopic weights differed slightly from whole numbers. See also **Aston Whole Number Rule**. From this he was led to the concept of the *packing fraction*, which is defined as the algebraic difference between the isotopic weight and the mass number, divided by the mass number. Although the theoretical significance of the packing fraction is difficult to assess, it does lead to some interesting conclusions with respect to nuclear stability. A negative packing fraction derives from a situation where the isotopic weight is less than the mass number, inferring that in the formation of the nucleus from its constituent particles, some mass is converted into energy. Since an equivalent amount of energy would be necessary to break up the nucleus into its constituent particles again, a negative packing fraction suggests a high order of nuclear stability. By the same reasoning, a positive packing fraction indicates nuclear instability. Stable elements with mass numbers above about 175 and below about 25 have positive packing fractions. It is interesting to note that the packing fractions of both hydrogen and uranium are positive.

Actually, a comparison of the isotopic weight with the mass number (as is done in determining the packing fraction) is somewhat artificial. A rigorous determination of the mass-energy interconversion in the formation of an atom would seem to require a calculation of the difference between the sum of the masses of the constituent particles of the atom and the experimentally measured isotopic weight. The value of the mass difference thus obtained is the *mass defect*. The energy equivalent of this mass difference as derived from the Einstein equation yields a measure of the binding energy of the nucleus. Division of the binding energy of a nucleus by the number of nucleons (the total number of protons and neutrons) therein yields the binding energy per nucleon. In stable isotopes, the binding energy per nucleon decreases with increasing mass number, a fact that is important in nuclear fission. Secondly, the binding energy per nucleon derived in the manner just described is an average value, whereas each additional nucleon added to the nucleus has a binding energy less than those that preceded it. Thus, the most recently added nucleons are bound less tightly than those already present.

Additional considerations regarding nuclear stability may be gleaned from a consideration of the odd or even nature of the numbers of protons and neutrons in the nucleus. According to the Pauli exclusion principle, no two extranuclear electrons having an identical set of quantum numbers can occupy the same electron energy state. See also **Pauli Exclusion Principle**. The application of this principle to the nucleus leads to conclusions which at least are not at variance with observations of nuclear stability. Thus, it is inferred that no two nucleons possessing an identical set of quantum numbers may occupy the same nuclear energy state. It would appear, then, that both protons and neutrons that differ only in their angular momenta or spins may exist in a nuclear state. The exclusion principle requires, therefore, that only protons having opposite spins can exist in the same state. The same consideration applies to neutrons. Accordingly, two protons and two neutrons might occupy the same nuclear energy state provided the nucleons in each pair have opposite spins. Such two-proton-two-neutron groupings are termed "closed shells," and by virtue of their proton-neutron interaction, they confer exceptional stability to nuclei they inhabit. The nuclear forces in closed shells are said to be "saturated", which means that the nucleons therein interact strongly with each other, but weakly with those in other states. Since like particles tend to complete an energy state by pairing of opposite spins, two neutrons of opposite spin, or a single neutron or proton also might exist in a particular energy state.

Any of the foregoing conditions may be achieved when the nucleus contains an even number of both protons and neutrons, or an even number of one and an odd number of the other. Since there is an excess of neutrons over protons for all but the lowest atomic number elements, in the odd-odd situation there is a deficiency of protons necessary to complete the two-proton-two-neutron quartets. It might be expected that these could be provided by the production of protons via beta decay. However, there exist only four stable nuclei of odd-odd composition, whereas there are 108 such nuclei in the even-odd form and 162 in the even-even series. It will be seen that the order of stability, and presumably the binding energy per nucleon, from greatest to smallest, seems to be even-even, even-odd, odd-odd.

Although the existence of binding energies holding the nucleus together has been demonstrated, the problem of defining the nature of these forces presents itself. Clearly, repulsive electrostatic forces must exist between protons. These are "long range" in effect. To achieve nuclear stability then, compensating attractive forces also must exist. It has been concluded that "short range" attractive forces exist between protons, between neutrons, and between protons and neutrons. The (p-n) attractive forces are considered to be of the greatest magnitude, while the (n-n) and (p-p) forces are of less intensity, with the latter decreased by virtue of electrostatic repulsion. When the number of protons in a nucleus is greater than 20, it is found that the ratio of neutrons to protons exceeds unity. The additional short- range attractive forces provided by the excess neutrons, therefore, may be considered as compensating for the long-range electrostatic repulsive forces between the protons. Nevertheless, when the number of protons exceeds about 50, the short-range forces are insufficient to counteract the electrostatic forces completely, with the result that the binding energy per each additional nucleon decreases.

The nature of the short-range attractive forces between nucleons requires further investigation. An interpretation of them has been presented by Heisenberg in terms of wave-mechanical exchange forces. Thus, if the basic difference between the proton and neutron in a system composed of these two particles is considered to be that the former is electrically charged while the latter is not, then the transfer of the electric charge from the proton to the neutron results in an exchange of individual identity, but not a change in the system. That is to say, the system still is composed of a proton and neutron, despite the fact that the particles have exchanged their identities. Since the system itself has the same composition, it must possess the same energy after the exchange as it did before. One of the principles of wave mechanics is that, if a system may be represented by two states, each of which has the same energy, then the actual state of the system is a result of the combination, i.e., resonance, of the two separate states and is more stable than either. In the proton-neutron system, the energy difference between the "combined" state and the individual states may be considered as the "exchange energy" or "attractive force" between the particles. In an extension of Heisenberg's proposal, Yukawa postulated that the exchange energy is carried by a particle termed the *meson*. Particles

having the properties attributed by Yukawa to mesons have been identified in cosmic rays.

With such concepts of nuclear structure and stability, however imperfect, the process of nuclear fission of uranium can be considered. Although fast neutrons (greater than 0.1 MeV) can cause fission in both uranium-235 and uranium-238, thermal neutrons (about 0.03 MeV) are effective only with uranium-235. Uranium-238 is unsatisfactory as a fissionable material for most purposes, however, since it has a high probability for "resonance capture" of fast neutrons, which is a non-fission process. It is instinctive to ponder why uranium-235 undergoes fission with thermal neutrons and uranium-238 does not. It will be recalled that the binding energy for an even-even nucleus exceeds that for an even-odd. Consequently, the addition of a neutron to uranium-235, which yields an even-even compound nucleus, will contribute a greater binding energy than in the case of uranium-238 where an even-odd compound nucleus would be produced. Calculations yield a value of 6.81 MeV for the additional neutron in the former case, and 5.31 MeV in the latter. Using Bohr and Wheeler's calculations, it is found that the activation energy for fission is 5.2 MeV for uranium-235 and 5.9 MeV for uranium-238. Thus, the binding energy for an additional neutron in uranium-235 exceeds its fission activation energy, whereas it is less in the case of uranium-238. It can be seen, then, that uranium-235 fission is energetically feasible with thermal neutrons while the fission of uranium-238 is not.

In considering the physical forces acting in fission, use may be made of the Bohr liquid drop model of the nucleus. Here it is assumed that in its normal energy state, a nucleus is spherical and has a homogeneously distributed electrical charge. Under the influence of the activation energy furnished by the incident neutron, however, oscillations are set up which tend to deform the nucleus. In the ellipsoid form, the distribution of the protons is such that they are concentrated in the areas of the two foci. The electrostatic forces of repulsion between the protons at the opposite ends of the ellipse may then further deform the nucleus into a dumbbell shape. From this condition, there can be no recovery, and fission results.

It will be recalled that the binding energy per nucleon decreases with increasing mass number, that is, a greater amount of energy is released in the formation of nuclei of intermediate mass number from their constituent nucleons than is the case of nuclei of high mass number. Thus, energy is released in fission because the binding energy of the high mass number uranium-236 compound nucleus is less than that of the intermediate mass number fission products which are produced. The total energy thus liberated in fission is about 200 MeV. Of this, the kinetic energy of the fission products accounts for 160 MeV. These fragments, being of significantly lower atomic number, require fewer neutrons for stability than they actually contain immediately after fission. These excess neutrons, therefore, are "boiled off" the fission fragments, the process occurring in two distinct phases. In the first phase, "prompt" neutrons of about 2-MeV energy are released within 10^{-2} seconds after fission occurs and take up about 7% of the fission energy. Subsequently, after several seconds, additional "delayed" neutrons with about 0.5-MeV energy are boiled off the fission products. See also **Energy**; and **Particles (Subatomic)**.

BINOCULAR. An instrument composed of two similar telescopes, one for each eye, usually with focusing tubes controlled by a common screw adjustment. The ordinary opera glass is a binocular utilizing Galilean telescopes. The field glass employs erecting telescopes of the spyglass type. A well-known modern form is the "prism binocular." The special feature of this instrument is a pair of right-angled, total reflection prisms in each telescope, which contribute three advantages. 1. The prisms, by means of two double total reflections in planes at right angles, accomplish the erection of the image without additional lenses. 2. The tube is rendered much shorter than in the ordinary field glass of equal power by the "doubling up" of the rays due to the reflections. 3. The objectives are by the same means set farther apart than the eyepieces, thus increasing the "stereo power" of the instrument as a binocular, so that objects can be seen to have depth or solidity at a greater distance than with the ordinary type. See Fig. 1.

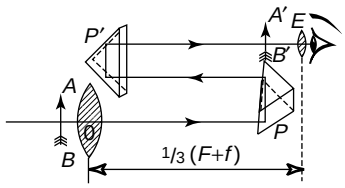

Fig. 1. Optical system of prism binocular.

BINOCULAR VISION. Having two eyes set at a distance apart, but with approximately parallel axes, enables a person to obtain two views from slightly different angles, and thus to become aware of the solidity of single objects and to get an idea of the actual distribution of different objects in space. To become vividly conscious of this faculty, one has only to look about the room for a time with a hand cupped over one eye, and then suddenly to remove the hand. If the vision is reasonably normal, it will be noticed that with one eye only the scene appears flat, like a photograph, but as soon as both eyes are used, objects spring into clear relief. In some manner the brain is able, through long experience, to blend the two different sensory pictures from the two different retinal images and to interpret the resulting sensation in terms of geometrical solidity. There is, however, a limit to the distance at which this impression is perceptible, and for very distant objects other factors must be relied upon, such as the apparent size (as of buildings or trees), or the opacity of the atmosphere (as in viewing distant mountains). In the absence of such factors, no estimate of distance can be formed; thus the stars all appear to be at the same distance. This limiting "stereoscopic radius" is for normal, unaided eyes, only 200 to 300 feet (60 to 90 meters), but with a binocular telescope, and especially with a prism binocular, it is increased in a ratio called the "stereo power" of the instrument.

An interesting aspect of the subject is the use of binocular pictures and the stereoscope. If one prepares two photographs or drawings of the same group of objects, from viewpoints approximately the same distance apart as human eyes (~2.75 inches; 7 cm) and mounted side by side on a card, so that each photo is viewed separately by the eye to which it corresponds, the observer gets the sensation of viewing a three-dimensional scene. Observation is facilitated by a pair of lenses designed to facilitate focusing the eyes for distance, and with a diaphragm set up between them to avoid seeing both pictures with either eye. This arrangement is the stereoscope.

BINODALS. Consider the volume-composition diagram of a binary mixture for states corresponding to the coexistence of a liquid and of a gaseous phase. If the temperature is below the critical region (see **Critical Point**) one obtains a diagram of the form represented in Fig. 1.

The line $V_A{}^g V_B{}^g$ corresponds to the molar volumes of the vapor phase, while $V_A{}^l V_B{}^l$ relates to the liquid phase. The lines such as $r^l — r^g$, $q^l — q$, etc., joining two phases in equilibrium are called binodals. In the critical region the diagram takes the form indicated in Fig. 2. K is the critical point. The curve $V_A{}^g — K — V_A{}^l$ is the *saturation curve*.

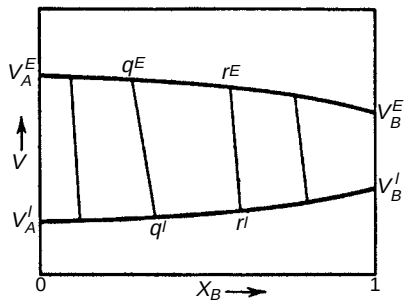

Fig. 1. Volume-composition diagram of a binary mixture below the critical region.

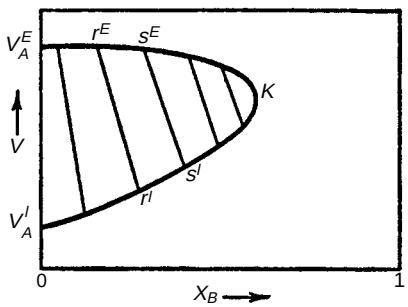

Fig. 2. Volume-composition diagram of a binary mixture in the critical region.

BINOMIAL DISTRIBUTION. If a trial can have one of two mutually exclusive results (say "success" and "failure") and if the probability p of a "success" is constant over a series of n independent trials, then the probability of obtaining r "successes" is

$$P_r = \frac{n!}{r!(n-r)!} p^r q^{n-r}$$

where $q = 1 - p$. This function is sometimes called the Bernoulli probability function, and the probability distribution of r is called the binomial distribution since the probabilities can be obtained by expanding $(q + p)^n$ by the binomial formula. The mean of the distribution is np, the variance npq. The negative binomial distribution has formally the same probability function but p and n are negative and n is not restricted to integral values.

BINOMIAL SERIES. The binomial theorem is a rule for expanding $(x + y)^n$, where n is a positive integer. The result is

$$(x+y)^n = x^n + nx^{n-1}y + \frac{n(n-1)}{2}x^{n-2}y^2 + \cdots + y^n$$

The $(k + 1)$th term is

$$\frac{n!}{k!(n-k)!}x^{n-k}y^k$$

but the coefficient is often indicated by $\binom{n}{k}$. It is called the binomial coefficient and equals the number of combinations of n things taken k at a time. Properties of the coefficients include

$$\binom{n}{0} = \binom{n}{n} = 1; \binom{n}{n} + \binom{n}{k+1} = \binom{n+1}{k+1}; \binom{n}{n-k} = \binom{n}{k}$$

If n is not a positive integer, an infinite series, called the binomial series, results. It converges absolutely for $|x| < 1$, diverges for $|x| > 1$. When $x = 1$, it converges for $n > -1$, diverges for $n \leq -1$, is absolutely convergent for $n > 0$; when $x = -1$, it is absolutely convergent for $n > 0$; divergent for $n < 0$.

If x is small enough, the quantity $(1 \pm x)^n$ may be approximated by $1 \pm nx; n = \pm 1, \pm 2, \pm 3, \ldots, \pm\frac{1}{2}, \pm\frac{1}{3}, \ldots, \pm\frac{3}{2}$, etc.

BINZ, CARL (1832–1913). Carl Biz was a German doctor, who was a pioneer in the field of scientific drug therapy (pharmacology) and who worked on remedies against malaria.

Binz, the son of a tobacco manufacturer, was born in Bernkastel, Germany. He studied medicine in Würzburg between 1851 and 1852. This university had a high reputation as it pioneered the introduction of scientific medicine, which was instigated in Germany in the second half of the nineteenth century. Teachers of Binz included such prominent professors as the pathologist Rudolf Virchow and the anatomist Albert Kölliker. In 1852, Binz proceeded with his studies at the University of Bonn, where he was taught among others by Johann Albers, who was a supporter of scientific experimental pharmacology. Having obtained his MD (1855), he worked at the Medical Clinic in Bonn. In 1859, he went to Naples, where he worked as a general practitioner. Thereafter, in 1861, he continued his medical education at the University of Berlin, which then stood at the forefront of German universities. In 1862, he went back to Bonn where he obtained his teaching license in pharmacology. He became assistant Professor in 1868 and full Professor in 1873. In Bonn, he built up the second pharmacological Institute in Germany in 1869. Binz retired in 1908.

With his knowledge of new research methodology, Binz performed basic investigations on the substance Chinin, which was, and still is, used in the therapy of malaria. Furthermore, he reintroduced alcohol, which had disappeared from the doctor's drug cabinet, into therapy. Binz was keen to apply drug research to medical practice. He promoted modern pharmacology with his textbook *Grundzüge der Arzneimittellehre*. Binz therefore contributed decisively to the introduction of scientific methods into drug research anddrug therapy.

BIOACCUMULATION. Bioaccumulation is a process by which a chemical from the environment accumulates in an organism's body over time. Bioaccumulation occurs when there is a concentration increase of the chemical in the tissues of an organism. Bioaccumulation results from mass equilibrium where the uptake of a chemical into the body of an organism exceeds the elimination of the chemical from the body. As such, a chemical that is eliminated immediately after uptake will not be bioaccumulated in an organism.

Uptake of a chemical means entrance of the chemical into an organism primarily from water or soil, directly or through consumption of foods that contain the chemical. A chemical can be taken up through roots or leaf surfaces in plants and by breathing, ingesting, or absorbing through the body surface in animals. Uptake of a chemical in plant cells can occur against its electrochemical potential gradient through the process of active transport. For example, selenate (SeO_4^{2-}) and arsenate (AsO_4^{2-}) are taken up via sulfate and phosphate transporters in the root plasma membrane, respectively.

The elimination of a chemical from an organism includes excretion and/or metabolism of the chemical. Elimination is the primary process by which an organism can reduce its chemical burden. Excretion is the removal of toxicants or excess chemicals from the body of plants or animals. A chemical taken up into the body of an animal can be eliminated by urination and defecation, whereas salt-tolerant halophytes can excrete sodium and other ions from their leaf surfaces.

A chemical can also be eliminated from an organism by transforming the original chemical into a new chemical, a process termed metabolism. Inorganic selenate can be taken up and biologically reduced or methylated into organic selenium compounds that can be volatilized into the atmosphere. Metabolism can also break down a large organic compound into small molecules or eventually mineralize the compounds into water, CO_2, and nutrients. Metabolism of an organic compound by an organism is termed biodegradation.

An organism's ability to take up or eliminate a chemical varies among species and depends on physiochemical properties of the chemical. Chemicals that are water-soluble will be taken up and readily eliminated by an organism. Persistent organic compounds are generally not water-soluble and are difficult for organisms to metabolize or degrade. These compounds tend to have a greater potential to accumulate in fat or lipid tissues.

Bioaccumulation can sometimes substantially increase the concentration of a chemical in the tissues of an organism. When the concentration of a chemical becomes higher in an organism than in the environment (e.g., water, soil, or air), the bioaccumulation process is specifically termed bioconcentration. The extent of bioconcentration can be expressed by the bioconcentration factor ($BF = C_{\text{org}}/C_{\text{env}}$), which is a ratio of the

concentration of a chemical in an organism (C_{org}) to the concentration of the same chemical in the living environment (C_{env}). If a plant species can accumulate an exceptionally high level of a metal (e.g., about 1% dry weight for zinc and manganese or 0.1% for copper and nickel in shoots) without having harmful effects, the species is termed a metal hyperaccumulator. *Astragalus bisulcatus* is a selenium hyperaccumulator that can accumulate about 0.5% (dry weight) of selenium in shoots.

A chemical that is bioconcentrated/bioaccumulated is not homogeneously distributed in the body of an organism. Distribution of an accumulated chemical varies significantly among tissues/organs, species, and chemicals. For instance, fat-soluble chemicals (e.g., polychlorinated biphenyls — PCBs) accumulate primarily in fat, cadmium in kidneys, and mercury in livers. Such organ-specific accumulation of a chemical may impose a potential hazard to an organism because the chemical can reach a critical body burden in those target organs. This can even occur in organisms that are exposed only to low levels of a toxicant in the environment.

Plant roots generally accumulate higher concentrations of metals (e.g., lead and manganese) than shoots. The distribution of a chemical in a plant can be described by its translocation factor ($TF = C_{shoot}/C_{root}$), the ratio of the concentration of the chemical in shoots (C_{shoot}) to the concentration in roots (C_{root}). A larger translocation factor means that a greater proportion of the chemical is accumulated in shoots compared to that in the roots. Similarly, the ratio of the shoot concentration (C_{shoot}) to the soil concentration (C_{soil}) of a chemical is termed the phytoextraction coefficient ($FC = C_{shoot}/C_{soil}$). Phytoextraction is one of the phytoremediation approaches using plants to remove toxicants from contaminated waters and soils. Plants with high phytoextraction coefficients can remove a large amount of pollutant by harvesting the chemical-laden shoots at contaminated sites.

One of the important environmental concerns associated with bioaccumulation is biomagnification, whereby the concentration of a chemical increases at each higher trophic level through a food chain. Biomagnification can result in a concentration increase of two to three orders of magnitude between two trophic levels. Therefore, due to biomagnification through the entire food chain, the concentration of a chemical in top predators may reach tens of thousands times the concentration in the water column. For example, through a water–plankton/algae–fish food chain at the Kesterson reservoir in Central California, selenium in fish was biomagnified 35,000 times from selenium-contaminated drainage water. Very high concentrations of selenium result in reproductive deformities and death of fish and waterfowl.

The term bioaccumulation is sometimes used to refer to the total amount of a chemical accumulated in the body of an organism. The amount of a chemical accumulated in an organ or tissue depends on both the chemical concentration and the actual biomass in which the concentration is determined. For example, a higher bioconcentration of selenium in *Astragalus bisulcatus* does not necessarily mean that a greater total amount of selenium from the environment can be accumulated in the plant because the species grows slowly and the total biomass production is small. To overcome such biological limitations, scientists are currently applying new biotechnology to combine the genome of a tolerant, slow-growing, selenium hyperaccumulator, such as *Astragalus*, with that of a less tolerant, but fast growing nonhyperaccumulator, for example, *Brassica juncea*, to develop a somatic hybrid plant that could increase the phytoremediation potential.

BIOASTRONAUTICS. The study of biological, behavioral, and medical problems pertaining to astronautics. This includes systems functioning in the environments expected to be found in space, vehicles designed to travel in space, and the conditions on celestial bodies other than on earth.

BIOCHEMICAL INDIVIDUALITY. The possession of biochemical distinctiveness by individual members of a species, whether plant, animal, or human. The primary interest in such distinctiveness has centered in the human family, and in the distinctiveness within animal species as it might illuminate some of the questions on human biochemistry.

While it has been known for centuries that bloodhounds, for example, can tell individuals apart even by the attenuated odors from their bodies left on a trail, the first scientific work which hinted at the existence of substantial biochemical distinctiveness in human specimens was the discovery of blood groups by Landsteiner about 1900.

A few years later Garrod noted what he called "inborn errors of metabolism" — rare instances where individuals gave evidence of being abnormal biochemically in that they were albinos (lack of ability to produce pigment in skin, hair and eyes), or excreted some unusual substance in the urine or feces. To Garrod these observations suggested the possibility that the biochemistry of all individuals might be distinctive.

About 50 years later serious attention to the phenomenon of biochemical individuality resulted in the publication of several articles and a book on this subject. (Williams, R. J.: *Biochemical Individuality*, Wiley, New York, 1956.) These reported evidence indicating that every human being, including all those designated as "normal," possesses a distinctive metabolic pattern which encompasses everything chemical that takes place in his or her body. That these patterns, like the abnormalities discussed by Garrod, have genetic roots is indicated by the pioneer explorations of Beadle and Tatum in the field of biochemical genetics in which they established the fact that the potentiality for producing enzymes resides in the genes.

Biochemical individuality, which is genetically determined, is accompanied by, and in a sense based upon, anatomical individuality, which must also have a genetic origin. Substantial differences, often of large magnitude, exist between the digestive tracts, the muscular systems, the circulatory systems, the skeletal systems, the nervous systems, and the endocrine systems of so-called normal people. Similar distinctiveness is observed at the microscopic level, for example in the size, shape and distribution of neurons in the brain and in the morphological "blood pictures," i.e., the numbers of the different types of cells in the blood.

Individuality in the biochemical realm is exhibited with respect to (1) the composition of blood, tissues, urine, digestive juices, cerebrospinal fluid, etc.; (2) the enzyme levels in tissues and in body fluids, particularly the blood; (3) the pharmacological responses to numerous specific drugs; (4) the quantitative needs for specific nutrients — minerals, amino acids, vitamins — and in miscellaneous other ways including reactions of taste and smell and the effects of heat, cold, electricity, etc. Each individual must possess a highly distinctive pattern, since the differences between individuals with respect to the measurable items in a potentially long list are by no means trifling. Often a specific value derived from one "normal" individual of a group will be several times as large as that derived from another.

BIOCHEMICAL OXYGEN DEMAND (BOD). A standardized means of estimating the degree of contamination of water supplies, especially those which receive contamination from sewage and industrial wastes. It is expressed as the quantity of dissolved oxygen (in mg/L) required during stabilization of the decomposable organic matter by aerobic biochemical action. Determination of this quantity is accomplished by diluting suitable portions of the sample with water saturated with oxygen and measuring the dissolved oxygen in the mixture both immediately and after a period of incubation, usually five days.

See also **Biodegradability**.

BIOCHEMICAL THEORIES OF AGING. Many cellular and biomolecular theories on aging share a common theme. As one proceeds through the litany of popular "error" -based theories one encounters this thread at a glance. "Wear and tear," "rate of living," "cross-linking," "free radical," "error catastrophe," and "somatic mutation" theories all trade heavily on normal biochemical processes that are known to generate potentially damaging molecular species known as free radicals. Generally speaking, these theories are all predicated on the effects of so-called

reactive "radical" intermediates on macromolecular targets such as DNA, protein, and lipids. The effects attributed to these include increases in protein cross-linking, oxidation of membrane lipids, and induction of genetic mutations. The downstream effects are thought to result in increased rates of aging and have been reported in various organisms as diverse as nematodes, flies, and humans

Free Radicals, Somatic Mutation, and Aging

There are more than 300 theories to explain the aging phenomenon. Many of them originate from the study of changes that accumulate with time. Among all the theories, the free-radical theory of aging, first postulated by Harman, is the most popular and widely tested, and is based on the chemical nature and ubiquitous presence of free radicals.

In 1956, Harmon introduced the free-radical theory of aging, proposing that free radicals generated as a function of normal metabolic stress can damage a variety of cellular macromolecules and may lead to aging (Harmon, 1956, 1981, 1992). Radicals that go unscavenged have been shown to damage cellular DNA and lead to mutations and cancer, as well as a variety of diseases that exhibit an aging component (Ames et al., 1993; Zs.-Nagy, 1992). Such radicals are routinely generated in a variety of cellular reactions that utilize oxygen such as mitochondrial respiration, the oxidative metabolism of a wide variety of substrates via the mixed function oxidase system (MFO) and the autoxidation of glucose. Indeed, of the four major endogenous processes that lead to significant DNA damage and mutation, oxidation appears to play the greatest role (Ames et al., 1992, 1993). DNA oxidation products can be readily detected in the urine as thymine glycol, thymidine glycol, hydroxymethyluracil, and hydroxymethyl deoxyuridine. Investigators have demonstrated that most of these metabolites (110 nmoles/animal/day) are derived from the repair of oxidized DNA from genomic and mitochondrial sources rather than contributions from diet or gut flora. This translates to an approximate daily burden of 10^4 DNA "hits" per cell in man and about 10^5 in the rat; approximately half of this comes from mitochondrial sources (Ames and Saul, 1988; Cathcart et al., 1984). Data further suggest that mitochondrial oxygen consumption in humans correlates with oxidative DNA damage as measured by 8-oxo-dG (8-oxo-7,8-dihydro-2'deoxyguanosine) which, in replicating DNA, may lead to G-T A-C transversions as well as other mutations (Loft et al., 1994). Interestingly, a strong negative correlation ($r = -0.91$) has been demonstrated between the maximum lifespan potential of various mammalian species and the rate of production of O_2^- and H_2O_2 by liver mitochondria (Sohal and Orr, 1992). That experimentally induced damage to mitochondrial membranes increases the production of H_2O_2 by the treated mitochondria (Sohal et al., 1990), further supports the possibility that age-related damage to mitochondria as a result of radical-induced injury may in turn result in an increase in the production of oxygen free radicals and an increase in the occurrence of somatic mutations (Takasawa et al., 1993).

The somatic mutation theory of aging was originally based on the observation that exposure to ionizing radiation reduced the lifespan of experimental animals (Burnet, 1974; Curtis, 1966; Orgel, 1973; Szilard, 1959). According to this theory, the age-related accumulation of somatic mutations could be expected to lead to a loss of irreplaceable cells or tissues, eventually compromising the health of the organism. Somatic mutation has, in fact, been implicated in a diverse array of human diseases associated with aging, including cancer, atherosclerosis and brain dysfunction (reviewed by Ames et al., 1993). Moreover, evidence suggests a relationship between somatic mutation, genetic instability, and aging in such progeroid syndromes as Ataxia Telangectasia, Cockayne syndrome, and Hutchinson-Guilford syndrome, all of which are characterized by DNA repair defects (Venema et al., 1990; Wang et al., 1991; Bernstein and Gensler, 1993). The recent positional cloning of a putative helicase gene in Werners syndrome further suggests the involvement of somatic mutation and genetic instability in aging (Yu, Chang-En et al., 1996).

Glycation

The chemical modification and cross-linking of proteins by the Maillard or "browning" reaction is thought to contribute to the aging of tissue proteins. Glycation is part of a process whereby the carbonyl of a reducing sugar (e.g., glucose) condenses with a reactive amino group in a target protein to form a Schiff base, which may further rearrange to form an Amadori adduct. These adducts may further degrade to form alpha keto-aldehydes which in turn react with proteins to form Maillard adducts also known as advanced glycation end products (AGE). These "browned" proteins, or Maillard adducts, are cross-linked and tend to be fluorescent (Wolff et al., 1993).

Advanced glycation end products are a heterogeneous group of molecules that accumulate in plasma and tissues with advancing age, diabetes, and renal failure. There is emerging evidence that AGEs are potential uremic toxins and may have a role in the pathogenesis of vascular and renal complications associated with diabetes and aging. These toxic molecules interact with specific receptors and elicit pleiotropic responses. AGEs accelerate atherosclerosis through cross-linking of proteins, modification of matrix components, platelet aggregation, defective vascular relaxation, and abnormal lipoprotein metabolism. *In vivo* and *in vitro* studies indicate that AGEs have a vital role in the pathogenesis of diabetic nephropathy and the progression of renal failure. The complications of normal aging, such as loss of renal function, Alzheimer's disease, skin changes, and cataracts, may also be mediated by progressive glycation of long-lived proteins. AGEs accumulate in renal failure as a result of decreased excretion and increased generation resulting from oxidative and carbonyl stress of uremia (Raj et al., 2000)

Determination of glycation and glycoxidation rates in skin collagen have been shown to predict longevity in ad libitum-fed (AL) and caloric restricted (CR) mice (Sel et al., 2000). C57BL/6NNia male mice were biopsied at age 20 months and at death. CR vs. AL significantly ($P < 0.0001$) increased both mean (34 vs. 27 months) and maximum (47 vs. 31 months) life spans. Markers of skin collagen glycation and glycoxidation rates reliably predicted early deaths in AL and CR C57BL/6NNia mice, strongly suggesting that an age-related deterioration in glucose tolerance is a life span-determining process mediated by the formation of Maillard adducts.

Alzheimer's disease (AD) is a progressive dementia affecting a large proportion of the aging population. The histopathological changes in AD include neuronal cell death and formation of amyloid plaques and neurofibrillary tangles (NFTs). AGEs are potentially toxic to neuronal cells, are present in brain plaques in AD. The extracellular accumulation of AGEs in AD may be caused by an accelerated oxidation of glycated proteins. AGEs participate in neuronal death by causing free-radical production: glycated proteins produce nearly 50-fold more radicals than non glycated proteins. Furthermore, interaction of AGEs with cells increases intracellular oxidative stress. Weakened anti oxidant defense mechanisms during aging may further lead to cell damage and death.

Decreased elasticity of the cardiovascular system and increased cataractogenesis are two more hallmarks of the normal aging process in mammals. A potential explanation is that collagen and lens crystallins become crosslinked during AGE formation. Previous studies have shown that aminoguanidine, an AGE inhibitor, can prevent glucose cross-linking of proteins and the loss of elasticity associated with aging and diabetes (Asif et al., 2000). BIOCHEMISTRY. The dawn of biochemistry may have been the discovery of the first enzyme, diastase, in 1833 by Anselme Payen. In 1828, Friedrich Wöhler published a paper about the synthesis of urea, proving that organic compounds can be created artificially, in contrast to the common belief of the time that organic compounds can only be made by living organisms. Since then, biochemistry has advanced, especially since the mid-20th century, with the development of new techniques such as chromatography, X-ray diffraction, NMR, radioisotopic labelling, electron microscopy and molecular dynamics simulations. These techniques allowed for the discovery and detailed analysis of many molecules and metabolic pathways of the cell, such as glycolysis and the Krebs cycle.

Originally a subdivision of chemistry but now an independent science, biochemistry includes all aspects of chemistry that apply to living organisms. Thus, photochemistry is directly involved with photosynthesis, and physical chemistry with osmosis — two phenomena that underlie all plant and animal life. Other important chemical mechanisms that apply directly to living organisms are catalysis, which takes place in biochemical systems by the agency of enzymes; nucleic acid and protein constitution and behavior, which are known to control the mechanism of genetics; colloid chemistry, which deals in part with the nature of cell walls, muscles, collagen, etc.; acid-base relations, involved in the pH of body fluids; and such nutritional components as amino acids, fats, carbohydrates, minerals, lipids, and vitamins, all of which are essential to life. The chemical organization and reproductive behavior of microorganisms (bacteria and viruses) and a large part of agricultural chemistry are also included in biochemistry. Particularly active areas of are nucleic acids, cell surfaces (membranes), enzymology, peptide hormones, molecular biology, and recombinant DNA.

BIOCHEMISTRY (The History). Biochemistry aims to explain biological phenomena in chemical terms. The problems are highly complex and until the twentieth century progress was slow and unreliable. During the eighteenth century chemistry was dominated by the phlogiston theory and the traditional method of organic analysis by destructive distillation provided no information about elementary composition. Both in theory and techniques therefore, chemistry was wholly inadequate to unravel the mysteries of the vital functions. Yet the importance of fermentation was recognized, photosynthesis was discovered and studies of animal respiration and digestion made useful contributions to early biochemistry. The complex chemical transformations occurring at moderate temperatures during the vital functions led to the belief that in living matter the ordinary laws of chemistry were modified by unknown vital forces. These controlled the special conditions pertaining to living matter, but when life was extinguished ordinary chemical forces once more came into play, resulting in decomposition and decay. Despite growing experimental evidence to the contrary, vitalism persisted among physiologists and chemists into the nineteenth century.

The displacement of phlogiston by oxygen from the late eighteenth century greatly facilitated progress. In addition, Antoine Lavoisier's experimental definition of the chemical element was accompanied by a more consistent use of the balance and a rational chemical nomenclature. Combustion analysis, first introduced by Joseph Louis Gay-Lussac in 1811, allowed the empirical formulae of organic compounds to be determined, although more accurate atomic weights were required for reliable results. Chemists analyzed plant and animal substances from the beginning of the nineteenth century, while physiologists and some physicians applied themselves to studies of the vital functions in health and disease. However, the development of biochemistry would also require later nineteenth-century advances in physical and organic chemistry. These included structural organic chemistry, electrochemistry, osmosis, colloid chemistry, stereochemistry and molecular energy studies together with physical techniques such as X-ray diffraction, electrophoresis, chromatography and labeling with radioisotopes.

Animal Chemistry

In the 1780s Lavoisier proposed a mechanism for photosynthesis by which plants take in carbon dioxide and release oxygen; he also began to investigate animal respiration. With Pierre Laplace he measured the heat evolved by small mammals, and similarities between combustion and respiration led him to locate the production of animal heat entirely in the lungs. William Prout, better known for his atomic hypothesis, also studied the vital processes. He thought that digestion and assimilation proceeded in stages involving the action of saliva, gastric juice, pancreatic juice and bile, followed by oxidation in the lungs, where the products of digestion were finally converted into blood. In 1824 Prout discovered hydrochloric acid in gastric juice and he later classified foods as saccharinous, albuminous and oleaginous (cf. carbohydrates, proteins and fats). See also **Digestive System (Human)**; and **Photosynthesis**.

Michel Eugène Chevreul investigated the nature of animal fats from about 1811. He showed that the fatty acids were analogous to inorganic acids and were capable of yielding salts with bases. Separating them using solvents, he identified each fatty acid by its melting point. The use of a physical constant as a criterion of purity and means of identification was an important step in the development of organic analysis. His results, published in 1823, showed that animal fats, although products of the vital functions were normal chemical compounds. See also **Fatty Acids (The History)**.

Jöns Jacob Berzelius and Justus Liebig were among the leading nineteenth-century chemists who advanced biochemistry. Berzelius analyzed animal solids and fluids; Liebig endeavored to extend Berzelius's work by creating a comprehensive metabolic theory. Beginning with the oxygen theory and his own organic analyses, Liebig described the assimilation of foods and the oxidation of muscle tissues releasing energy and excretory products like urea and uric acid. For three decades after its publication in 1842, Liebig's *Animal Chemistry, or organic chemistry in its application to physiology and pathology* stimulated chemical and physiological research. Unfortunately, Liebig was no physiologist and most of those who tried to find supporting evidence for his theories failed. By about 1870 Liebig's theories had been almost entirely superseded, but the research they engendered helped to advance biochemistry and some nineteenth-century chemists even applied Liebig's ideas successfully. For example, Henry Bence Jones discovered proteins now known to be part of the autoimmune system and Ludwig Thudichum identified some important biochemical substances, including hematoporphyrins in the blood and the main chemical constituents of the brain.

Cell Theory

In 1838 Theodor Schwann, originator of the cell theory in biology, suggested that fermentation occurred only in living yeast cells. Liebig refused to accept this and proposed an alternative chemical theory of fermentation but Louis Pasteur, opposing Liebig's chemical theory, showed that fermentation depends on the vital functions of living yeast cells and bacteria. The controversy was resolved in 1872 when Pasteur's work

received general recognition. See also **Pasteur, Louis (1822–1895)**; and **Schwann, Theodor Ambrose Hubert (1810–1882)**.

Close links between plant and animal life have been identified. Animal metabolism is ultimately dependent on the assimilation of plant material and consequently photosynthesis studies have made important contributions to the elucidation of animal metabolism. In 1817 J. Pelletier and J. B. Caventou suggested the name "chlorophyll" for the green substance common to all plants. The connection between chlorophyll and starch in growing plants was recognized in1862 when Julius von Sachs, a German plant physiologist, suggested that starch in green plants is produced from carbon dioxide and water. In the early years of the twentieth century chromatography revealed two forms of chlorophyll and in 1914, Richard Willstätter and Arthur Stoll showed that both are esters of dibasic acids with methyl alcohol and phytol, a hitherto unknown unsaturated, aliphatic alcohol ($C_20H_{39}OH$). Further investigation of photosynthesis showed that it involved a chemical and a photochemical step. The chemical step is associated with the formation of a chlorophyll–carbon dioxide compound and the photochemical step involves the formation of a peroxide which is then decomposed by an enzyme to yield oxygen, formaldehyde and reconstituted chlorophyll. See also **Chlorophylls**.

About 1860 Moritz Traube suggested that to understand the chemistry of life required a correct theory of fermentation. His "ferments" were oxygen-rich agents derived from proteins. In 1878 Willy Kühne coined the term "enzyme" for Traube's ferments. Enzyme action had first been observed in 1833 when Anselme Payen and Jean François Persoz isolated a compound (diastase) which converted starch into sugar. Three years later pepsin was extracted from the stomach wall by Schwann. These discoveries preceded Berzelius's notion of catalysis (1837) which, he predicted, would prove important in plants and animals where complex reactions took place at very moderate temperatures. Further investigation of fermentation resulted in a distinction between "organized" ferments such as yeast and "unorganized" ferments including the enzymes, the biological catalysts, but in 1877 Felix Hoppe-Seyler suggested that there was no fundamental difference between them. Twenty years later Eduard Buchner fermented a sugar solution with a cell-free extract of yeast. This discovery showed that the contents of the cells, rather than their life processes, caused fermentation. This led to a theory of fermentation based on enzyme action and provided the key to the study of cell chemistry. See also **Buchner, Eduard (1860–1917)**; and **Hoppe-Seyler, Ernst Felix Immanuel (1825–1895)**.

Liebig's idea that animals are incapable of biosynthesis was challenged in the 1850s by Claude Bernard's discovery of the glycogenic function of the liver. In 1867 Carl Voit tried to revive Liebig's theory of the direct assimilation of proteins, but Eduard Pflüger, Professor of Physiology at Bonn, argued that there were constitutional differences between food proteins and tissue proteins. In the 1870s he demonstrated the importance of intracellular respiration; a discovery embraced by Bernard, and suggested a theory of indirect nutrition, whereby animal cells synthesize complex substances from simpler nutrient molecules derived from food. Bernard postulated an internal environment within the cells, where chemical degradation and synthesis takes place. According to Bernard all the principles necessary for the maintenance of animal life are released into the blood. Respiration introduces oxygen; digestion introduces the necessary nutrients together with the secretions of the various organs. The blood is the carrier of all these substances and the cells absorb from it only what they require to maintain the vital functions occurring inside them. The circulation and secretions together ensure, besides the renewal of the internal environment, the removal of waste products, and all these changes are regulated and harmonized by the nervous system, maintaining a steady state (homeostasis).

Bernard's theory of the internal environment marks a watershed in the history of biochemistry. It put an end to theories of direct assimilation, replacing them with the breakdown of complex food molecules into smaller nutrient constituents from which new compounds specific to the needs of each cell were synthesized. This theory prefigured one of the most important discoveries of modern molecular biology — the coded program of protein synthesis –but Bernard's ideas of indirect nutrition and the internal environment were too advanced for many of his contemporaries. Much detailed research was needed to establish them and it was due to British and American scientists including W. M. Bayliss, E. H. Starling, C. S. Sherrington, J. S. Haldane, J. Barcroft, W. B. Cannon and L. J. Henderson that the concept of the internal environment was elaborated from the beginning of the twentieth century. See also **Barcroft, Joseph (1872–1947)**; **Bayliss, William Maddock (1860–1924)**; **Cannon, Walter Bradford (1871–1945)**; **Haldane, John Scott (1860–1936)**; **Henderson, Lawrence Joseph (1878–1942)**; **Sherrington, Charles Scott (1857–1952)**; and **Starling, Ernest Henry (1866–1927)**.

Biological Oxidation

It has been recognized from the beginning of the nineteenth century that energy is released during biological oxidation, though the mechanisms by which this was brought about remained in doubt. When C. F. Schönbein discovered ozone in 1840 he suggested that the first step in biological oxidation was the conversion of oxygen to ozone. This idea led to the popular nineteenth-century "ozone craze." Later, in 1903, A. N. Bach and R. Chodat discovered the enzyme peroxidase in plant cells and it was thought that peroxides caused biological oxidation in a two-stage process. In the first stage the enzyme oxygenase formed peroxides; in the second stage peroxidase used these peroxides to oxidize other organic compounds. This theory dominated ideas on biological oxidation until about 1920. Although based on plants, it was widely thought that the oxygenase–peroxidase system also accounted for respiration in animal tissues. It was later found that oxygenase is itself an enzyme (catechol oxidase) capable of oxidizing catechol and similar compounds to quinones and that peroxidase cannot use these as oxidizing agents.

From 1920 another theory of biological oxidation was proposed, based on the respiratory systems in yeast, bacteria and animal tissues. According to this theory, oxygen atoms were first activated by combination with iron atoms in a hemoprotein enzyme. Otto Warburg called this the "respiratory ferment;" it would later be identified as cytochrome oxidase. A rival school considered that the organic molecules were activated rather than oxygen and that most biological oxidations were dehydrogenations brought about by a new group of enzymes, the dehydrogenases. These have turned out to be the most important factors in biological oxidations; there are now well over 150 known dehydrogenases. By studying these two opposing systems using spectroscopic techniques David Keilin followed the course of respiratory changes in the mitochondria of cells. He discovered the oxidative cytochromes in 1925 and identified many intermediate steps in cell respiration. See also **Warburg, Otto Heinrich (1883–1970)**.

In 1906 Arthur Harden and W. J. Young observed that the addition of a soluble phosphate to a fermenting sugar solution caused the rate of fermentation to increase. The additional carbon dioxide and alcohol formed was proportional to the quantity of phosphate added and the phosphate was converted into a hexosephosphoric acid. These observations were important for metabolic studies in the mid-twentieth century, which have shown that most vital functions depend on enzyme action. The hydrolytic processes catalyzed by enzymes break down starch, fats and proteins into simpler molecules (monosaccharides, fatty acids and amino acids) which then enter complex metabolic pathways also controlled by enzymes. During these processes energy is released, providing animal heat or to be stored for later use in muscular exertion. One of the principal aims of twentieth-century biochemistry has been to discover the details of these metabolic pathways. Considerable progress has been made, though many details still require further elucidation. See also **Harden, Arthur (1865–1940)**.

In 1907 Walter Fletcher and Frederick Gowland Hopkins published the first reliable quantitative data on the proportions of lactic acid in muscle tissue. Lactic acid was known to take part in the biochemical transformations of carbohydrates, linking them with proteins and fats, but these two workers now recognized that its role in the metabolism of animal tissues is pivotal. However, they did not discover that lactic acid holds an intermediate position between sugar and alcohol in the metabolism of muscle tissue. See also **Hopkins, Frederick Gowland (1861–1947)**.

In the early years of the twentieth century Gustav Embden had isolated several intermediate metabolic products from muscle tissues, including adenyl phosphoric acid, also found in the liver. Embden was the first to discover and link together all the steps in the conversion of glycogen to lactic acid. Between 1919 and 1921 Otto Meyerhof, recognizing that muscle is the only tissue in which it is possible to compare the chemical changes occurring with the work done or heat energy evolved, investigated lactic acid formation in muscle tissue as a measure of work done. This led to the glycogen–lactic acid cycle, and made a fundamental contribution to the understanding of muscular action. In all but the briefest, most intense muscular contractions additional adenosine triphosphate (ATP), an important energy-carrying coenzyme, is supplied by the chemical reactions of the glycolytic, or Embden–Meyerhof–Parnas, pathway, particularly

applicable to rapid muscular action. In this, the change from glucose to lactate is coupled with the formation of ATP from adenosine diphosphate (ADP). If not immediately required, the energy is stored in the muscle. ATP is created in greater abundance than the numbers of carbohydrate, fat or protein molecules metabolized, creating more of this energy-rich compound than is required for immediate needs. The excess energy is stored in muscle tissue as phosphocreatine, a labile compound that readily absorbs and releases phosphate groups. See also **Meyerhof, Otto Fritz (1884–1951)**.

$$\text{Phosphocreatine} + \text{ADP} \rightarrow \text{creatine} + \text{ATP}$$

$$\text{ATP} - \text{1phosphate group} \rightarrow \text{ADP} + \text{energy}$$

$$\text{Creatine} + \text{1phosphate group} \rightarrow \text{phosphocreatine}$$

The lactate, a waste product, diffuses out of the muscle to be transported by the blood to the liver where most of it is converted into glycogen. The rate of oxidation of lactic acid is regulated by the rate of respiration. In prolonged strenuous exercise lactic acid is formed faster than it can diffuse out of the muscle and this results in muscle fatigue. Glycogen from the liver is reversibly converted into glucose and finds its way into the bloodstream, thus completing the cycle.

In the 1930s Warburg investigated the relation between the chemical and photochemical steps in photosynthesis using the effects of intermittent illumination on the green unicellular alga *Chlorella*. His work led to a study of the cytochromes. Warburg and Keilin independently examined the respiratory function of the cytochromes and showed that the respiratory chain in the cells was located in the mitochondria. Alternate oxidation and reduction could be traced through chains of cytochromes, each reducing the next in line until the last, identified as the respiratory ferment, reacted with oxygen. At each stage the small quantities of energy released are stored in high-energy bonds such as the phosphate link in ATP. The whole complex system was summarized in the Krebs cycle, the metabolic pathways of which have been subjected to minute and intensive research ever since. It also became clear that other substances besides the cytochromes were involved and in 1932 Axel Theorell working with Warburg, isolated the first so-called "yellow enzyme" composed of a protein and the nonprotein yellow coenzyme riboflavin (vitamin B_2). Keilin isolated the oxidative enzyme cytochrome *c* and proposed a new explanation of the action of the cytochromes involving activated hydrogen as well as oxygen. These investigations were carried out on heart-muscle preparations, but similar reactions have been detected in the cells of plants, microorganisms and fungi. Thus, they represent a common feature shared by all forms of life. They were essential early stages in the elaboration of the citric (or tricarboxylic) acid cycle proposed by Sir Hans Krebs in 1937. In animal cells the enzymes specific to each step are located in the mitochondria, in plant cells they are found in the chloroplasts, and in microorganisms they are found in the cell walls. See also **Krebs, Hans Adolf (1900–1981)**.

A fuller elaboration of the citric acid cycle came after 1940 with the discovery that the three principal food constituents, carbohydrates, fats and proteins, all yield a common product, coenzyme A. This forms citric acid which is then broken down into carbon dioxide and water with the liberation of coenzyme A once more. At each intermediate step in this metabolic chain, hydrogen atoms are transferred from one carrier to another and small quantities of energy are released. Thus, the citric acid cycle is the source of energy refurbishment supporting all the vital processes.

Enzyme reaction rates vary widely and depend on activators, or coenzymes, ranging from simple metal ions such as Ca^{2+} or Mg^{2+} to complex organic molecules such as vitamins. In 1960 it was found that the coenzyme in energy-producing processes, ATP, is itself fabricated in the cells by a protein enzyme, ATP synthase. The molecular structure of ATP synthase was partially determined in 1994 after 12 years of research. In addition to providing fresh knowledge about how living things produce energy, it is thought that this research may throw new light on the processes of ageing and the causes of degenerative diseases. The large molecules of carbohydrates, fats and proteins are broken down into smaller molecules such as pyruvates, free fatty acids and amino acids, all of which take part in the mechanisms of the citric acid cycle and thus link the metabolic transformations of carbohydrates, proteins and fats. Enzymes are now known to control most biochemical processes, from the breakdown of complex molecules like carbohydrates and proteins during animal metabolism to the synthesis of macromolecules within the cells. Most enzymes have a protein structure and most work with one or more coenzymes, but certain other complex molecules not regarded as enzymes, such as messenger RNA, also show catalytic properties. See also **Enzyme**.

Structural Organic Chemistry

Before the details of such cellular mechanisms could be fully explored, far more information about the chemical structures of large molecules was needed. Thus, progress in biochemistry had to await the development of structural organic chemistry.

In 1815 J. B. Biot found that certain natural oils rotated the plane of polarized light. The same substance could exist in two forms both having the same empirical formula, yet capable of rotating the plane of polarized light in opposite directions. The problem facing organic chemists was to correlate optical activity with molecular configuration. The fundamental discovery required to solve this problem was Kekulée's recognition in 1858 that the carbon atom is tetravalent. Using this, J. H. Van't Hoff suggested in 1874 that structural formula must be three-dimensional. A compound in which a central carbon atom is attached to four different substituents in a tetrahedral structure would have two non-superposable forms one of which is the mirror image of the other. Applying this concept Pasteur investigated molecular asymmetry in the tartrates by separating potassium tartrate crystals mechanically. Optical activity was later used by Emil Fischer to identify the many stereoisomers of the sugars.

In 1885 Fischer observed that phenylhydrazine ($C_6H_5.NH.NH_2$) forms well-defined crystalline compounds (osazones) with the sugars and this allowed him to identify the molecular structures of 16 stereoisomers of glucose. Before 1891 it had been necessary to assume a configuration for each sugar, but from that year onwards Fischer applied himself to the problem of assigning specific configurations to each isomeric sugar molecule and by 1896 he had done so for all the monosaccharides. He retained the straight-chain formulae devised by H. Kiliani, though later studies by W. N. Haworth and others showed that they contain lactone rings. Fischer also examined the degradation of sugars by enzymes and from his study of the saccharases he recognized the specificity of enzymes and concluded that the enzyme and its substrate were related as a key to its lock. Later work has shown this concept to be true to a degree Fischer himself could hardly have suspected.

Fischer's other major contribution to structural organic chemistry concerned his elucidation of the molecular structures of the purines, amino acids and proteins. Even before he began work on the sugars Fischer had been engaged in a study of three purine derivatives, caffeine, theobromine and xanthine, all structurally related to uric acid. Ludwig Medicus had given the correct formula for uric acid in 1875; Fischer confirmed it by synthesis. Between 1882 and 1900 he isolated about 130 purine derivatives, thus extending Liebig and Friedrich Wöohler's 1838 studies of the oxidation products of uric acid. Fischer attempted to correlate the molecular structures of these compounds with their physiological properties. Later, in 1914, he returned to this work and succeeded in preparing the first synthetic nucleotide, theophylline d-glucose phosphoric acid, thus linking his work on sugars with his studies of the purines. This work was a first step leading to the study of the nucleo-proteins. Fischer also investigated polypeptides and simple proteins, showing how amino acids are combined in protein molecules. By 1907 he had synthesized a polypeptide containing 18 amino acids. Its molecular weight was 1213 and he calculated that there would be 816 possible optical isomers. See also **Amino Acids**.

In 1877 Traube suggested that enzymes are related to proteins, but the isolation of pure enzymes only began in the 1920s. Jackbean urease was the first enzyme to be crystallized in a pure state, by J. B. Sumner in 1926. J. H. Northrop, who isolated several proteolytic enzymes, crystallized pepsin in 1930. Both were found to be complex proteins and little could be done to determine their structures until special methods were developed. The sequence of amino acids in proteins was later found using a method devised by Frederick Sanger for determining the order of the 51 amino acids in the insulin molecule in about 1950. Another group of biological compounds, the hormones, has also caused considerable difficulty for structural organic chemists in the twentieth century. Those hormones, which like glucagon are polypeptides, have posed problems in the elucidation of their amino acid sequences, but others have been found to be based on the characteristic ring structure of the sterols containing 17 carbon atoms and 28 hydrogen atoms arranged in four rings. See also **Northrop, John Howard (1891–1987)**; **Sanger, Frederick (1918–Present)**; and **Sumner, James Batcheller (1887–1955)**.

Hormones and Endocrinology

In the nineteenth century it was recognized that glands such as the spleen, thymus, thyroid and adrenals secrete specific substances which are carried by the blood to other organs in the body. Towards the end of the nineteenth century a number of discoveries revealed the essential nature of these secretions for animal health and it became common to connect the lack or excess of specific endocrine secretions with certain diseases. Adrenaline ($C_9H_{13}O_3N$) was discovered in 1894 in experiments on the blood pressure of a dog. A little later vasopressin, a peptide hormone released from the posterior lobe of the pituitary gland, was discovered. This is also capable of increasing the blood pressure. Adrenaline was isolated independently in 1901 by T. B. Aldrich and J. J. Abel in America and shortly before by J. Takamine in Japan. In 1902 William Bayliss and Ernest Starling identified the substance secretin, produced by epithelial cells in the stomach during digestion. This is released into the bloodstream and in the pancreas it causes the secretion of pancreatic juice. Thus, secretin was recognized as a chemical messenger, produced in one organ and carried by the bloodstream to the organ it is intended to stimulate. Starling introduced the term "hormone" to describe such chemical messengers in 1905. However, as secretin is a polypeptide of moderate molecular weight, Bayliss and Starling were unable to isolate it, much less determine its molecular structure. The existence of a number of other mammalian hormones was surmised, but they all proved difficult to isolate and synthesize and only a few had been characterized. It is now known that hormones fall into three main classes: steroids, peptides and proteins, and amino acid derivatives. See also **Adrenaline and Noradrenaline**; **Bayliss, William Maddock (1860–1924)**; and **Starling, Ernest Henry (1866–1927)**.

Hormone secretion is controlled by the pituitary gland situated at the base of the brain. There are three main divisions of this gland, although the whole complex organ weighs only about one gram in the human adult. During the 1920s work on the pituitary gland led to the isolation of six different protein hormones, four of which were found to stimulate other endocrine glands. Since then other hormones have been isolated, several of which control the sexual functions; others govern the rate of growth and the chemical or physiological balance in the animal body. The chemical structures of all have been determined and their chemical syntheses achieved. See also **Pituitary Gland**.

Adrenaline, a derivative of catechol, was the first hormone to be synthesized in 1904; thyroxin, the active principle of the thyroid gland, first isolated by E. C. Kendall in1914, was synthesized by C. R. Harington and G. Barger in 1926–1927. Thyroxine, stored in the thyroid gland as a protein, is hydrolyzed by thyrotrophin, another hormone produced by the pituitary body. Thus one hormone calls another into action. Thyroxine is mainly concerned with the consumption of oxygen and thus the metabolism of all the cells and tissues in the body; it appears to increase the production of a number of enzymes. In 1922 Frederick Banting and Charles Best identified and prepared the pancreatic hormone, insulin, for therapeutic use in diabetes. J. J. Abel obtained crystals of insulin in 1926, but Dorothy Hodgkin using X-ray diffraction elucidated the molecular structure of insulin only in the 1960s. This work complemented Sanger's earlier determination of the complete amino acid sequence for bovine insulin. Sanger's methods opened the way to the determination of the structures of many other complex proteins. He later applied radioisotope labeling using ^{32}P and other techniques to determine the sequencing in ribonuclease synthesized in the early 1960s. The pancreas also produces another hormone, glucagon, a polypeptide containing 29 amino acids in a known sequence. See also **Banting, Frederick Grant (1891–1941)**; **Diabetes Mellitus**; **Hodgkin, Dorothy Mary Crowfoot (1919–1994)**; and **Sanger, Frederick (1918–Present)**.

The chemical structures of the steroid hormones produced by the adrenal glands and the sex organs are related to cholesterol. They are all very similar and even small structural changes in their molecules produce profound physiological effects. The steroid hormones secreted by the adrenal cortex control carbohydrate and mineral metabolism; some are concerned with the formation of glucose from proteins and enable the body to withstand stresses such as intense heat or cold, injury and infection. The hormones of the adrenal cortex control carbohydrate and mineral metabolism in the body. Similar compounds, though with more complex structures, are produced by the thyroid gland. Work on the sex hormones was carried out from about 1926. In 1929–1930 Edward Doisy in America, Guy Marrian in Britain and Adolf Butenandt in Germany isolated from the urine of pregnant women two ovarian hormones related to sterol. Butenandt also isolated androsterone from male urine and in 1934 Leopold Ruzicka in Switzerland obtained this hormone from cholesterol. These biologically active substances are metabolites of the ovaries and testes, respectively. The differences in their molecular structures and physiological actions are relatively slight; both are fat soluble. See also **Butenandt, Adolf Friedrich Johann (1903–1995)**; **Doisy, Edward Adelbert (1893–1986)**; and **Ruzicka, Leopold Stephen (1887–1976)**.

The anterior pituitary gland influences the rate of secretion of the hormones of the adrenal cortex, the gonads and thyroid gland. Its action is influenced by nerve centers in the hypothalamus, the part of the brain immediately above the pituitary gland. The secretion of hormones and the functions they control are therefore coordinated by the nervous system. In some cases there is a "feedback" mechanism whereby the secretions of one endocrine gland stimulates or damps down secretions from another. Thus a circle of action and reaction exists between some of the endocrine organs as the balance of hormone secretion is maintained.

The effects of injecting adrenaline are similar to those induced by stimulation of the sympathetic nervous system and this led to the suggestion that the liberation of adrenaline at sympathetic nerve endings might transmit the excitatory or inhibitory impulse to the effector cells of muscles or glands. Thus it seemed that certain hormones might control the functions of the central nervous system. It is now thought that a large number of chemicals can act in this way, but only a few have been so far identified. The first of these, noradrenaline, was isolated by Hans van Euler in 1946. Others include acetylcholine, dopamine and serotonin. Acetylcholine was first isolated in 1914; its function in slowing the heartbeat was identified in 1921 by Otto Loewi, a German physiologist. See also **Central and Peripheral Nervous Systems**.

In the 1930s it was observed that one hormone can act in opposition to another. Fréedéeric Houssay in Argentina found that extracts of the anterior pituitary gland combat the action of insulin. Frank Young found that administration of anterior pituitary extract causes a persistent diabetic condition. Cyril Long and Francis Lukens discovered an antagonism between insulin and the secretions of the adrenal cortex. These and other observations that hormones can act against each other have proved useful in elucidating the endocrine control of the vital functions and in medical and surgical treatments of certain conditions. However, it is now known that the substance present in an endocrine gland does not necessarily take the same form as that of the hormone in the blood. Furthermore, hormones may themselves undergo metabolic changes, either in the blood or in the tissues, before they are able to cause reactions in the cells or in the enzymes they influence. Thus, increased knowledge in endocrinology has created a situation in which the precise chemical definition of a hormone has become a matter of some difficulty.

Vitamins

Although dietary deficiencies have long been recognized as the cause of certain diseases, the search for vitamins (a term introduced by Casimir Funk) began about 1912. Gowland Hopkins observed that animals fed on a sufficient quantity of purified foods ceased to grow unless a small amount of milk was added. This drew attention to the "vitamin" question, though for several years the real existence of these elusive dietary factors was disputed. See also **Hopkins, Frederick Gowland (1861–1947)**.

In 1915 Elmer McCollum and M. Davis identified fat-soluble A and water-soluble B as essential accessory dietary factors in rats. These were later named vitamins A and B respectively. The latter was found to prevent beriberi, while lack of vitamin A retarded growth and caused increased liability to infection of the respiratory system. The antiscorbutic vitamin C was later identified and in 1922 lack of fat-soluble vitamin D was recognized as the cause of rickets. About the same time vitamin E was identified. In 1926 it was discovered that pellagra is a vitamin deficiency disease. The vitamin in this case seemed to accompany the anti beriberi factor, but was different from it, in that it was much more stable to heat. In 1927 the anti beriberi factor was labeled vitamin B_1 and the heat-stable factor became vitamin B_2. This was at first thought to be a single compound, but was later found to be a complex including riboflavin, a yellow pigment with growth-promoting properties found in milk. In 1934 pyridoxine, another component of the B_2 complex was identified. Nicotinic acid and nicotinamide (niacin and niacin amide), the anti-pellagra factor, were identified in 1937. For several decades additional vitamins were discovered. Three are of particular importance for human blood: vitamin K promotes the formation of prothrombin in the liver, folic acid prevents

anaemia and vitamin B_{12} (cyanocobalamin) is the anti-pernicious anaemia factor. See also **McCollum, Elmer Verner (1879–1967)**; and **Vitamin**.

Each of the four fat-soluble vitamin groups, A, D, E and K, includes several related compounds with biological activity. All contain one or more units of an isoprene structure in their molecules ($-C{=}CH-C.(CH_3){=}CH-$). These vitamins are transported by lymph from the intestines to the blood. Bile salts are required for their efficient absorption. They may be taken up as esters of palmitic acid or combined with a protein. Vitamins A, D and K are stored chiefly in the liver; vitamin E is found in body fat. The action of the fat-soluble vitamins is connected with certain enzymes. Some carotenes also show vitamin A activity. Only α and β carotenes and tryptoxanthin are important in human metabolism and β carotene is the most active. Water-soluble vitamins include vitamin B_1 (thiamin), B_2 (riboflavin), B_3, B_6 (pyridoxine), niacin, vitamin B_{12}, folic acid, pantothenic acid and biotin. In metabolic processes they act as coenzymes. Thus, vitamins B_1, B_2 and B_6 become phosphates, biotin undergoes a change in structure and nicotinic, pantothenic and folic acids form esters. Water-soluble vitamins are not stored in the body to the same extent as fat-soluble ones and any excess is excreted in the urine. In addition to the true vitamins there are other substances with vitamin activity such as choline and *p*-amino benzoic acid, but these are fabricated in the body, as well as occurring in foods, and are not considered true vitamins.

Blood Chemistry

The difference in color between venous and arterial blood was known in ancient times, but that the same blood changed color as it circulated from veins to arteries through the lungs was discovered by William Harvey in the 1620s. The cellular structure of the blood was also first observed in the seventeenth century. The red blood cells attracted most attention and in the nineteenth century it was realized that they were the oxygen carriers. In 1827 Hans Fischer and his co-workers synthesized a large number of porphyrins, the chemical components of the red cells, and showed how they transport oxygen in the blood. As the only fluid circulating through all the organs, the blood was thought to transport nutrients and remove waste products, maintaining homeostasis in the body, fundamental to Bernard's theory of the internal environment. In 1862 Hoppe-Seyler observed the characteristic absorption spectrum of oxyhemoglobin and in the same year William Stokes demonstrated the oxidation–endashreduction of the pigment present in the red cells. The nature of the active part of hemoglobin and the structure of the porphyrin ring was investigated by Ernst Küster in 1913. Max Perutz and John Kendrew determined the complete structure of the hemoglobin molecule using X-ray spectrographic techniques between 1937 and 1959. See also **Fischer, Hans (1881–1945)**; **Harvey, William (1578–1657)**; **Hoppe-Seyler, Ernst Felix Immanuel (1825–1895)**; **Kendrew, John Cowdery (1917–1997)**; and **Perutz, Max Ferdinand (1914–2002)**.

The white blood cells, or leucocytes, include a proportion of phagocytes, cells that engulf and digest bacteria, protecting the body from disease. In addition, 20–25% of the white cells, the lymphocytes, combine with antigens and remove them from the body, so controlling infections. There are two types of lymphocytes, called B cells and T cells. The B cells produce chemical antibodies on activation by antigens and release them into the bloodstream. In the 1970s the Japanese immunologist Susumu Tonegawa showed that about 1,000 pieces of genetic material in the antibody-producing part of B lymphocytes can be shuffled and recombined in different sequences, enabling up to 1 billion different types of antibodies to be formed each specific to a different antigen. See also **Lymphocytes**.

Serum albumin accounts for 55% of the total protein in blood plasma. Its main function is to help maintain the osmotic pressure between blood vessels and tissues. Circulating blood tends to force blood out of the blood vessels and into the tissues, but the colloidal nature of albumin and to a lesser extent of other blood proteins, the globulins, keeps the blood within the blood vessels. Albumin also contains two materials necessary for the control of clotting: antithrombin keeps the clotting enzyme thrombin from working unless needed and heparin cofactor is necessary for the anticlotting action of heparin. The fate of cholesterol, another chemical substance found in the bloodstream, was investigated by Henri V. Goldstein in 1972. He found that low-density lipoproteins, the primary cholesterol-carrying particles, are withdrawn from the bloodstream into the body's cells by receptors on the cells' surface. Although dealing with complex chemical substances and processes, studies on the blood tend to be physiological and immunological, rather than biochemical. They form part of medical research and it is in such areas that the overlap between biochemistry, medical chemistry and physiology highlights the difficulties of demarcation and the precise definition of biochemistry as an independent discipline. See also **Anticoagulants**; **Blood**; and **Blood Clotting: General Pathway**.

Molecular Biology and the Nucleic Acids

Since the 1950s progress in biochemistry has been led by "molecular biology," a subject concerned with the ultimate physiological organization of living matter at the molecular level. It is virtually impossible to distinguish between biochemistry and molecular biology, since both are concerned with intermolecular transformations within living cells. Since its inception in the late nineteenth century biochemistry has sought to develop a molecular biology in stark contrast to the macrobiology of organs and tissues. Yet modern molecular biology seeks recognition as a separate discipline concerned with the molecular basis of inheritance (genetics) and with protein synthesis in the cells. It has developed from and is related to biochemistry, yet distinct from it. In 1950 W. T. Astbury identified molecular biology with a study of the forms of biological molecules, their development through higher levels of organization and their relationship with genesis and function. The first part of this definition is conformational, the second is informational and for some years these two aspects of molecular biology were studied independently. See also **Molecular Biology**.

By the end of the nineteenth century biochemists had come to recognize that complex biological molecules held the key to understanding vital processes in living cells. But, as the methods of classical chemistry were inadequate to determine the structures of large molecules such as proteins, polysaccharides or nucleic acids, biochemists concentrated on the transformations of smaller molecules forming the components of these complex molecules. Molecular biologists, on the other hand, adopted physico-chemical techniques such as X-ray diffraction, developed in the 1920s at the Royal Institution in London by W. H. Bragg who built up a school of crystallography including Astbury, J. D. Bernal and Kathleen Lonsdale. Using this technique it was discovered that the structures of complex molecules could be determined, but even this was simpler than the problems of explaining their functions in terms of their structures. Astbury applied X-ray crystallographic techniques to fibres and discovered that when a natural fiber such as hair is stretched, its diffraction pattern changes due to molecular rearrangements in its structure. Bernal turned to other living materials and with Dorothy Hodgkin and Perutz obtained diffraction patterns for large crystalline protein molecules. Perutz analyzed the structure of the hemoglobin molecule and Kendrew made the first three-dimensional analysis of the molecular structure of myoglobin. ATP synthase, an enzyme responsible for synthesizing ATP, the universal energy carrier in living cells, was also examined. In the 1930s, however, further progress was impossible due to the inadequacy of contemporary methods of analysis. See also **Kendrew, John Cowdery (1917–1997)**; and **Perutz, Max Ferdinand (1914–2002)**.

In America it was recognized that the helix was a common structural form for large molecules. As X-ray diffraction analysis was unable to cope with such a structure Linus Pauling suggested that model building would offer the only hope of solving these difficult problems. For success, however, precise inter-atomic distances and angles were required. Pauling therefore applied X-ray diffraction techniques to the analysis of amino acids and small peptides in order to determine their dimensions with minute accuracy. By the late 1940s he was able to use his results to construct models of large protein and polypeptide molecules by combining these smaller units. From this work a general theory of the diffraction of X-rays by helical structures was evolved. This would be very important for determining the structures of the nucleic acids. During the same period another group of workers settled on the study of bacteria, believing that the bacteriophage was an ideal subject for the study of heredity because the transfer of hereditary material was not confused by other biological functions such as metabolism. The so-called "phage group" was indifferent, even hostile, to chemistry and perhaps due to this attitude it was only in 1944 that it was realized that the materials under study were actually nucleic acids. See also **Pauling, Linus Carl (1901–1994)**.

The British and American researchers were proceeding independently of each other until James D. Watson, a post-doctoral student from the phage group, came to work in Cambridge. Watson was working on DNA (deoxy ribonucleic acid), a compound first isolated from pus cells in 1869. Its significance as genetic material was recognized in 1944 when it was observed

that bacterial DNA changed the genetic material of other cells. In 1953 Francis Crick and Watson proposed the double helix structure for DNA, providing the conceptual framework for understanding DNA replication and protein synthesis. It appeared that the DNA molecule was composed of two helical phosphate-sugar chains running in opposite directions and crosslinked at regular intervals by four organic bases always appearing in pairs (thymine–adenine and cytosine–guanine). The links between the chains are formed by relatively weak hydrogen bonds and the separation of the chains leaves each one as a template for duplication using the small molecules brought to the cells by the blood. See also **Crick, Francis Harry Compton (1916–2004)**; and **Watson, James Dewey (1928–Present)**.

In 1955 S. Ochoa in Spain discovered an enzyme, polynucleotide phosphorylase, capable of synthesizing ribonucleic acid (RNA). It was later found that this enzyme degrades RNA in the cells, but under test-tube conditions it runs its natural reaction in reverse. The enzyme has enabled understanding of processes whereby hereditary information in genes is translated through RNA intermediaries into enzymes that determine the functions and character of each cell. With discoveries such as these the "informational" molecular biologists could proceed without further help from the chemical conformationists who were free to move on to other structural problems. See also **Ochoa, Severo (1905–1993)**.

Although the way in which molecular biology apparently developed seems to fit this simple scenario, it is incomplete. The development of molecular biology includes many more aspects of biochemical research like plant viruses such as *Tobacco mosaic virus*. These can be readily extracted from plants and crystallized; they all contain RNA. The mechanisms of nuclear division have also been important, as has the role of RNA in protein synthesis. The contributions of these and other lines of biochemical research cannot be ignored in considering the origins of molecular biology. In 1978 the New York Academy of Arts and Science held a meeting to promote a broader view focusing attention on the history of protein research. Since then developments in molecular biology have involved such important advances as the first complete synthesis of a protein, the detailed mapping of the arrangement of atoms in certain enzymes, the elucidation of intricate mechanisms of metabolic regulation and the molecular action of hormones. These lines of investigation are closely related to medical research and prominent recent researchers in molecular biology are largely drawn from this field. They include immunologists Caesar Millstein and Georges Kohler, geneticists Christiane Nusslein-Volhard and Eric Wieshaus, and Hugh Esmor Huxley, who proposed the sliding filament theory of muscle contraction. See also **Milstein, Cesar (1927–2002)**.

BIOCHORE. 1. As used by W. Köppen in his 1931 climatic classification, the part of the earth's surface that is able to support plant life. It is bounded on the one hand by the cryochore, or region of perpetual snow, and on the other by the xerochore, or waterless desert. Transition zones on either side are the bryochore, or tundra region, and the poëchore, or steppe region. The bulk of the biochore consists of the dendrochore, or treed region. See also **Biosphere**; and **Climatic Classification**.

2. In ecology, a group or region of similar plant and/or animal life.

BIOCLIMATOLOGY. The study of the relations of climate and life, especially the effects of climate on the health and activity of human beings (human bioclimatology) and on animals and plants.

BIODEGRADABILITY. The susceptibility of a substance to decomposition by microorganisms, specifically the rate at which detergents and pesticides and other compounds may be chemically broken down by bacteria and/or natural environmental factors. Branched-chain alkylbenzene sulfonates (ABS) are much more resistant to such decomposition than are linear alkylbenzene sulfonates (LAS), in which the long, straight alkyl chain is readily attacked by bacteria. If the branching is at the end of a long alkyl chain (isoalkyls), the molecules are about as biodegradable as the normal alkyls. The alcohol sulfate anionic detergents and most of the nonionic detergents are biodegradable. Among pesticides, the organophosphorus types, while highly toxic, are more biodegradable than DDT and its derivatives. Tests on a number of compounds gave results as follows. Easily biodegraded: *n*-propanol, ethanol, benzoic acid, benzaldehyde, ethyl acetate. Less easily biodegraded: ethylene glycol, isopropanol, *o*-cresol, diethylene glycol, pyridine, triethanolamine. Resistant to biodegration: aniline, methanol, monothanolamine, methyl ethyl ketone, acetone. Additives that accelerate biodegradation of polyethylene, polystyrene, and other plastics are available. See also **Detergents**.

BIODEGRADATION. The beginnings of life on this planet arose during a time of extreme conditions. For life to arise in an inhospitable world, the first organisms needed to be simple but hearty. The life forms of today considered most similar to those early ancestors of life are bacteria and archaea — simple, primitive organisms. Despite their primitive nature, these organisms have a diverse and powerful metabolic potential.

As life and other processes transformed the earth's air, land, and water, early organisms were in a new and changing environment. A wider variety of ecological niches became available. For five-sixths of the earth's existence, it was inhabited exclusively by microorganisms. Given their short generation time, microorganisms have had unfathomable generations to adapt to earth's many chemicals. As a result it is quite possible that for every natural compound that exists, there is a microorganism that has evolved to metabolize it and use it for growth.

Microorganisms are at the base of the food chain and play a key role in both secondary production and in decomposition. The ability of microorganisms to decompose or breakdown compounds is known as biodegradation. This term is often used to refer to the degradation of environmental pollutants by bacteria or fungi. This discussion will focus on the degradation process itself and the factors that influence and limit biodegradation.

Microbial Diversity and Metabolic Potential

The use of biodegradation to remove a contaminant from the environment is known as bioremediation. Understanding microbial diversity and metabolic potential are essential to understanding how to use biodegradation for remediation projects. During the twentieth century, a vast number of synthetic and natural compounds were released into the environment. A complex community of microorganisms often has the mechanisms to use or detoxify many of the compounds that humans have released. See also **Bioremediation**; and **Water Pollution**.

Some organisms have a very narrow range of metabolic potential, and others have a wider capacity. For example, it has been demonstrated that the organism *Pseudomonas putida*, strain F1, degrades approximately 105 compounds, and it has been suggested that it can degrade many more. Other compounds, many of which are synthetic, are resistant to microbial degradation. Resistant compounds are known as recalcitrant compounds; many factors contribute to a compound's recalcitrance, which will be discussed later.

Many synthetic compounds are considered xenobiotics. The term xenobiotic is often used to refer to compounds that are foreign to biological

systems. The term originates in mammalian systems, not microbial systems. It does not always describe a compound accurately in microbial terms, because microbial diversity is so vast. What is foreign to one group of bacteria may be readily metabolized by a different group.

Microorganisms benefit from biodegradation by metabolizing a compound to yield carbon and energy. Energy is derived from the transfer of electrons and the conservation of that energy in the form of molecules such as adenosine triphosphate (ATP) and nicotinamide-adenine dinucleotide (NAD^+). ATP conserves this energy through high energy phosphate bonds and is used to drive energy-requiring reactions in the cell. NAD^+ is an electron carrier involved in oxidation–reduction reactions. If metabolism results in complete breakdown of a compound to inorganic products such as CO_2 and H_2O, this is referred to as mineralization. As the compound of concern disappears from the environment, the number of organisms that use this compound as a substrate for metabolism increases. This is known as growth-linked biodegradation, and mineralization is a common result.

Enrichment Cultures and Biodegradation Research

When research scientists attempt to identify an organism capable of degrading a particular compound, they collect microorganisms from the environment and inoculate them into a culture flask containing minimal medium, and the compound of interest provides the sole carbon source. The minimal medium provides other nutrients, such as nitrogen and phosphorous, that are necessary for microbial growth. Organisms unable to use this compound will not be able to grow, whereas those that can metabolize the compound will flourish. The organisms for this enrichment culture are often collected from a site where the compound of interest is found naturally or as a contaminant. For instance, if a researcher were attempting to isolate a xylene-degrading microorganism, a sample might be collected from an area of a gasoline spill because xylene is a component of gasoline.

Scientists need to be cautious of optimism because one organism may seem to degrade a chemical efficiently under laboratory conditions, but the actual environment where the degradation is to take place may have many inhibiting factors that cannot be controlled.

It is important for researchers to identify degradation products because some products are more toxic than the parent compound. For example, the hydrolysis of the herbicide 2,4-D is catalyzed by soil microorganisms, which yields a form of the compound toxic to plants.

Factors Limiting Biodegradation

The mere presence of a compound and a capable microorganism does not guarantee the compound's degradation. Microbial growth requires water, nitrogen, phosphorous, trace elements, carbon, energy, temperature, and suitable pH conditions. Biodegradation commonly supplies the carbon or energy or both. But growth may be inhibited by other toxins or limited by other essential elements or conditions. Under environmental conditions, predation can also be a factor that limits biodegradation. Protozoa consume bacteria; bacteriophage are viruses that can infect and lyse bacteria.

If no organisms can use the compound as the sole carbon or energy source, a compound may still be cometabolized. Cometabolism involves the degradation of a compound by an organism without providing carbon, energy, or any other factors required for growth. Unlike mineralization, cometabolism is not growth-linked. Even though the compound is not functioning as the carbon or energy source, it is possible for degradation to be quite rapid. Often other organic molecules in the environment provide the carbon or energy source, which leads to an increase in the microbial population that is responsible for the increased rate of degradation.

Enzymatic Mechanisms

The proper enzyme must exist for metabolism or transformation of a compound. Over geologic time, microorganisms have adapted to compounds and structures to which they are exposed regularly. It is often believed that microbial enzymes have not evolved rapidly enough to cope with the onslaught of synthetic compounds that have been released into the environment in the last century.

Biodegradation may occur inside or outside of the cell. Intracellular enzymes require the organism to have some means of transporting the compound inside the organism for degradation. Extracellular enzymes are released by the organism and degrade the compound before the products are transported into the cell, where the final degradation occurs. This is a common microbial tactic when the carbon or energy source is too large to internalize. Extracellular enzymes are manufactured in comparatively high concentrations compared to intracellular enzymes.

TABLE 1. COMMON FUNCTIONAL GROUPS IN CONTAMINANTS

Name	Structure	Example(s)
Halogen	R–X where X=Cl, Br, or F.	Metolachlor
Aromatic ring		Benzene, toluene, ethylbenzene, xylenes (BTEX), polyaromatic hydrocarbons (PAHs)
Carboxcylic acid		Picloram
Alkene	$R_1-C=C-R_2$	Aldrin, dieldrin, and heptachlor
Alcohol (hydroxyl group)	$HO-R_1$	2,4-D
Ester		Malathion
Ether	R_1-O-R_2	2,4-D, MTBE

Degradative enzymes are often highly specific for a particular reaction. The enzyme must be able to fit the correct molecular structure into its active site. The active site of an enzyme is responsible for the cleavage or molecular rearrangement of a portion of the compound. The three-dimensional structure of the functional group fits neatly into the active site of the enzyme. Functional groups are often the targets of these enzymes (Table 1). Compounds can have a combination of functional groups, and the transformation of these compounds will depend on the spatial arrangement of the functional groups and the enzyme's ability to catalyze the the degradation products. If it is known that an organism can degrade a structurally similar compound, then it may be possible to enrich for an organism capable of degrading the compound of concern.

Acclimation Phase

Initially, the organisms in the environment that can degrade a particular compound will often be insufficient to cause a noticeable change in the quantity of compound present. This initial period, referred to as the acclimation phase, can vary in length among compounds, environments, and organisms. Bioavailability and compound concentration can influence the length of the acclimation phase. If the compound is present in the environment at a concentration that is too high, then it can be toxic to organisms that would break it down.

Research has shown that organisms that have been exposed to a particular compound can respond more quickly to a second exposure to the same compound. The first exposure selects for a community of organisms capable of degrading the compound. Upon reintroduction of that same compound, the community is already capable of degrading the compound, and the acclimation phase is shortened. The shortened acclimation phase can be attributed either to a more metabolically active community or a more rapid increase in the number of organisms capable of degrading the compound. This response has been identified among organisms capable of degrading several different pesticides.

Recalcitrance

Recalcitrant molecules are either resistant to degradation or are degraded at a very slow rate. There are several reasons that this occurs. As suggested previously, it is possible that the necessary enzyme does not exist. It is also possible that the correct enzyme may exist, but it cannot reach the active site and catalyze the necessary reaction. Finally, the enzyme necessary for the degradation of the compound may never be turned on by the organism. In this case, the enzyme is encoded on the organism's DNA, but no signal induces enzyme production. Some compounds, such as 2,4-D, are readily degraded under aerobic conditions but not under anaerobic conditions. Other compounds, such as the organophosphate herbicide, fenitrothion, are preferentially degraded under anaerobic conditions. Thus, the environment can play a role in a compound's recalcitrance.

Bioavailability

A compound must be bioavailable before degradation will occur. The organism and its enzymes must be capable of coming into contact with the compound. To understand fully the limitation that bioavailability presents, we need to examine the microscopic scale on which microorganisms exist. Most bacteria are no longer than 10 μm, and the distance between one soil particle and another may be a journey that a bacteria never makes. Most bacteria in soil or sediment are attached to particles, but some are motile. These motile organisms often simply pass through pore spaces and do not really contribute to the microenvironment. If examined in great detail, it would be possible to see that the surfaces of soil and sediment particles consist of depressions and valleys, which provide habitats for native microorganisms. Some microorganisms will never leave these tiny spaces. These organisms rely on the movement of compounds and nutrients for survival. Some pores are too small for microorganisms but are large enough to provide a protective area for the compound.

Over time, the bioavailability of a compound tends to decrease due to sequestration of the compound. When the compound is plentiful, microorganisms will use the molecules that are easiest to obtain. Available compound is used, whereas the excess becomes bound to soil and sediment particles. Compound bioavailability then limits biodegradation. Researchers have attempted to model the diffusion and sorption of a compound to soil or sediment. One model is the diffusion–sorption bioavailability model that attempts to describe the rate of biodegradation in the presence of soil or sediment aggregates. Many biodegradation studies are done in flasks and do not take into account environmental factors such as diffusion and sorption.

Nonaqueous Phase Liquids and Compounds of Low Water Solubility

Nonaqueous phase liquids (NAPLs) generally have low water solubility. Dense nonaqueous phase liquids can be found below an aquifer, whereas light nonaqueous phase liquids are found on the surface of the water. A very small fraction of a NAPL is soluble in water, and this quantity is available to microorganisms for biodegradation. The vast majority of NAPLs are not in the aqueous phase, so they are often considered unavailable to the organisms capable of degrading or metabolizing them, thus presenting a factor limiting biodegradation. NAPLs that have polluted the environment include hydrocarbons (mainly from oil spills) and industrial solvents.

Microbial growth on compounds of low water solubility is generally slow; however; in some cases, exponential growth has been observed. There are several ways by which a compound that has low water solubility can be degraded. The small fraction of the compound that enters the aqueous phase is readily accessible to the organism. The organism also can come in direct contact with the compound at the water–compound interface. Finally, some organisms can make the compound more accessible through a process known as pseudosolubilization. Pseudosolubilization occurs via compounds released by the organism, which act as carrier molecules. The compound becomes enclosed in a micelle, which may diffuse through the aqueous phase. Microorganisms in the aqueous phase can then use the carbon source within the micelle. Surface active compounds can also be released by the organism. These compounds are composed of various lipids and interact with low solubility compounds such as hydrocarbons to facilitate their uptake by the organism.

Groundwater Bioremediation

Groundwater contamination is of high priority because so many people rely on groundwater as a source of drinking water. Porosity, the empty space between soil and sediment grains, determines how much water an aquifer can hold. Water moves slowly through underground aquifers and that movement is a function of the type of soil or rock that composes the aquifer. Darcy's law allows scientists to approximate the discharge of water from an aquifer and takes the material that makes up the aquifer and the hydraulic gradient into consideration. Once the plume is located and the concentration of compound has been determined, removing it can be difficult and costly.

For in situ biodegradation to occur, it is often necessary to supply oxygen and nutrients to the microorganisms. The absence or presence of oxygen can make a substantial difference to the active microbial community and its ability to degrade the contaminant. The contaminated groundwater can also be pumped from the ground into a reactor, where microorganisms degrade the contaminant (for a review, see Langwaldt and Puhakka Ref.). These reactors function similarly to sewage treatment plants. Contaminated groundwater and nutrients are pumped into a reactor where microorganisms are grown so that they are attached to the reactor. As the contaminated groundwater passes the microorganisms, they degrade the compound. The water is then disposed of or returned to the aquifer. Bioreactors are often limited by their high costs. Pumping of NAPLs is often difficult due to their low solubility in water.

Marine Oil Spills

Marine oil spills can be remediated by bioremediation. Dispersants are used to spread the nonaqueous phase contaminants across the water's surface to create more favorable biodegradation conditions. The dispersants themselves are biodegraded in the process. It is estimated that 50% of the oil from the Exxon Valdez spill was biodegraded on the water surface, on the shore, or in the water column. Fertilizers are often used to enhance the rate of oil degradation and to supply otherwise limiting nutrients.

Algal Bioremediation

Biodegradation is not limited only to bacteria. Fungi play an important role in soil systems; in many aquatic systems, algae can play an important role. Several algal species are capable of degrading some pesticides in fresh water systems. Algae can be used to clean industrial pulp mill effluent before the effluent is discharged. They are effective in removing both the dark color of the effluent and organic halides. Some algae can bioaccumulate some polycyclic aromatic hydrocarbons in marine systems. Bioaccumulation is the sequestration of a compound by an organism, where the compound remains unchanged and the organism is unharmed by its presence. Over time, significant quantities of compound can be accumulated by the organism. See also **Bioaccumulation**.

The metabolic diversity of microorganisms is a powerful tool for degrading of unwanted compounds. Numerous sources are available to provide additional information regarding biodegradation processes. The journal *Biodegradation*, published quarterly, contains scientific advancements in biodegradation. Biodegradation databases are available that provide information on biodegradable compounds and the enzymes and microbial species that degrade them. A useful database is the University of Minnesota Biocatalysis/Biodegradation Database, found on the web at: http://umbbd.ahc.umn.edu/.

BIODIVERSITY. See **Wetlands**.

BIODYNAMICS. The study of the effects of dynamic processes (motion, acceleration, weightlessness, etc.) on living organisms.

BIOELECTROCHEMISTRY. Application of the principles and techniques of electrochemistry to biological and medical problems. It includes such surface and interfacial phenomena as the electrical properties of membrane systems and processes, ion adsorption, enzymatic clotting, transmembrane pH and electrical gradients, protein phosphorylation, cells, and tissues.

BIOGENIC ICE NUCLEUS. An ice nucleus of biological origin, particularly bacteria (e.g., pseudomonas syringae) from plant surfaces. These organisms have threshold temperatures as high as $-2\,^{\circ}\mathrm{C}$ ($28\,^{\circ}\mathrm{F}$), being active at the highest temperature known for natural nuclei. They were first identified in leaf litter, collected worldwide. Commercial application lies in nucleation of water spray drops for artificial snow on ski slopes.

BIOGEOCHEMICAL CYCLE. See **Meteorology**.

BIOGEOCHEMISTRY. A branch of geochemistry dealing with the interactions between living organisms and their mineral environment. It includes, among other studies, the effect of plants on weathering of rocks, of the chemical transformations that produced petroleum and coal, of the concentration of specific elements in vegetation at some time in the geochemical cycle (iodine in sea plants, uranium in some form of decaying organic matter), and of the organic constituents of fossils.

BIOGEOGRAPHY (The History). Biogeography is the study of the large-scale distribution patterns of flora and fauna. Modern studies date from the nineteenth century when biologists realized that former changes in the geology and geography of the globe helped plants and animals expand or contract their range. Evolutionary ideas, and then the notion of continental drift, became key concepts.

JANET BROWNE, Wellcome Trust Centre for the History of Medicine, London, UK

Introduction

Although many of the concepts basic to modern biogeographical thought can be discerned in the past, the words "biogeography" and "ecology" were not in common usage before the twentieth century: these are retrospective labels for systems of ideas that were not clearly demarcated in earlier times. Indeed it is debatable whether biogeography, the study of the large-scale patterns of floras and faunas across the globe, ever really became established as a distinct biological science. Post-Darwinian biogeographical concepts have mostly been subsumed into other subject areas. Before Darwin they merged seamlessly with what we now call ecology. Ecology, as it was first defined, denoted a science that dealt with the ways in which living things interact locally with each other and with the environment. Ernst Haeckel coined the word "oecologie" in *Generelle Morphologie* (1866). As such, this notion had a long history, reaching back at least as far as Linnaeus' concepts of the "polity," "balance," or "economy"of nature, and was magisterially addressed in Alexander von Humboldt's, Augustin De Candolle's and Alphonse De Candolle's successive accounts of the environmental factors that influenced plant distribution. It was only in the opening decade of the twentieth century, however, that ecology consolidated into the shape that it has today: even then it was racked by controversy and dispute over its guiding principles. Biogeography, on the other hand, was closely connected with theories of evolution proposed in the middle of the nineteenth century. See also **Ecology (The History)**; and **Haeckel, Ernst Heinrich Philipp August (1834–1919)**.

Early History

Ideas about the distribution of animals and plants across the globe have of course a very ancient history. Taking the study of animal and plant geography at its most basic level, it is readily apparent that little attempt at understanding the regionality of the natural world could have been undertaken without some knowledge–either accurate or misleading–about the existence of different organisms in different areas. Ever since the great age of European geographical exploration that opened with the epic figure of Henry the Navigator and encompassed Vasco da Gama, Columbus, Magellan and Drake, and led on to the voyages, among others, of La Condamine, Pallas, Cook, Vancouver and Humboldt, great emphasis was laid in Europe on the significance of collecting the native fauna and flora of new regions and on bringing specimens back for cataloguing and future assessment. Without these raw materials natural philosophers had little to go on.

Early biogeographical thought was therefore intimately tied up with travel and access to exotic specimens. Ideas of what might constitute a regional fauna or flora, and complementary ideas about the pattern they might make over the surface of the globe, were at heart rooted in a generalized concern with acquiring and understanding foreign species.

Linnaeus (Carl von Linné) was one of the first to make this concern scientifically explicit. Linnaeus catalogued many thousands of foreign organisms that were received by him in Uppsala, Sweden, and issued definitive lists of indigenous species. In this way, he expressed in scientific form the commonplace notion of biological "regions," each with its characteristic plants and animals. Linnaeus popularized the words "fauna" and "flora" to signify a regional unit as well as the genre of books in which such plants and animals might be catalogued. His disciples traveled extensively, sending back remarkable collections of plants to further this work. In fact Linnaeus, who was a devout Protestant and believer in the divine creation of species, liked to think of himself as a second Adam, naming and describing the fruits of God's handiwork. He considered that a museum collection was one way to bring back together all the species that God originally created in the Garden of Eden. See also **Linnaeus, Carl (Linné) (1701–1781)** ; and **Plant Sciences (The History)**.

Many other scholars during the eighteenth century were interested in animal and plant distribution. Some tried to fit their knowledge into a biblical scheme, puzzling over the migration routes that animals may originally have taken from Mount Ararat when they disembarked from Noah's Ark. Some daringly suggested that animals and plants were created where they were nowadays found. The most influential proposal was the scheme set out, in rather scattered form, by Georges-Louis Buffon in his *Histoire naturelle, générale et particulière* (1749–1804) (Natural History: General and Particular). Buffon suggested that the earth was much older than usually supposed, some 75,000 years. In his scheme animals originated very early on, and probably in the arctic circle when the earth was much warmer, and had subsequently dispersed southwards. When the animals came to rest they adapted to local environmental factors such as climate. For example, he thought native American species had "degenerated" from the original form under the influence of heat. Therefore the general similarities between the faunas of each major landmass, lions in Africa being similar to pumas in America and tigers in Asia, could be explained by the original population having dispersed from the north and then diverged according to the environment. The existence of these "representative" species was subsequently dubbed "Buffon's law." Buffon's theory not only reflected the environmentalist view widely accepted during the French Enlightenment it also endorsed a secular view of the origin and history of animals. However, his ideas about animal geography formed only a small part of his all-embracing theory of the natural world. See also **Buffon, Georges Louis (1707–1788)**.

Nineteenth-Century Studies

The fifty or sixty years between Buffon and Charles Darwin were remarkable in Europe and North America for the number and variety of theories relating to both the large-scale and small-scale distribution of animals and plants. Almost everyone who worked with natural material–including fossils–had something to say about the geographic patterns that could be discerned, the means of dispersal, or the defining physical features of local habitats. Key concepts emerged, most notably in Alexander von Humboldt's *Essai sur la géographie des plantes* (1807) (Test on the geography of plants), which drew on his adventurous exploration of the River Orinoco and its environs in 1799–1804. Intellectual focus shifted specially to plant geography because of plants' obvious restriction to certain areas. See also **Humboldt, Alexander von (1769–1859)**.

Humboldt was exquisitely alert to the subtle shifts in vegetation over a vast area like the Orinoco basin. As he explored the mountain ranges

in Central America, he identified the characteristic bands of plant life that exist at successive heights on a mountain. He called this the "physionomie" of vegetation; and correlated zones of plant life with carefully calibrated physical, chemical and environmental measurements. In a series of illustrations he mapped the slopes of Mount Chimborazo and compared its belts of vegetation with those of mountains at higher latitudes (Mont Blanc, France and Mount Sulitelma, Norway). He noted that these altitudinal belts mimicked latitudinal vegetation zones; for example, the "physionomie" of the summit flora of Chimborazo resembled the Siberian tundra. Humboldt's observations were supported by a wealth of physical data that indicated where any particular plant might live, including the degree and angle of insolation, latitude, rainfall, temperature range, barometric pressure and so on. His scientific explorations provided the information he needed for these large- and small-scale comparisons.

Several sophisticated assessments of vegetation followed thereafter. Botanists were quick to appreciate that distinct communities of plants, such as coniferous forest, deciduous woodland, heath or moorland, were associated with particular environmental conditions. In particular, Augustin De Candolle's *Essai élémentaire de géographie botanique* (1820) provided a significant guide. De Candolle's definition of the "stations" (local distributions) and "habitations" (provinces) of plants encouraged many naturalists to investigate the conditions required for life, concerning themselves with the nature of the soil, climate, frost, elevation, and the amount of sunshine in different areas. The natural habitation of rice, De Candolle explained, was India; its station was marshland. See also **de Candolle, Augustin-Pyramus (1778–1841)**.

From these studies emerged a general consensus about dependency distribution. Later on, Alphonse De Candolle brought work in this area to a climax in his mighty *Géographie botanique raisonnée* (1855), the cornerstone of mid-century ideas on the subject. This major contribution to the field was unfortunately overshadowed by Darwin's *Origin of Species* (1859). Alphonse De Candolle believed in the creation of most species by divine fiat, but he also suggested there must be a degree of variation and speciation under diverse physical conditions such as those experienced by species living in isolation on an oceanic island. He was keenly interested in adaptation to environmental factors. Although there were no comparable outstanding treatises on zoological geography to match his synthesis of contemporary botanical work, there were a number of useful articles on zoogeography published in the scientific journals of the day.

Less obviously, these environmental studies paralleled similar concern in France, Germany and Britain with the medical problems of expatriate Europeans abroad. Fevers, contagious diseases, parasites and nonspecific disabilities related to tropical life were regarded as "the white man's burden" and much medical and official government anxiety was expressed during this period over the Europeans' apparent inability to cope physically with foreign climes. A solid interest in medical geography, and in human geography, emerged. This interest was taken up in particular by ethnographic and missionary societies. James Cowles Prichard notably summarized these and other contemporary views on geographical distribution from a historical perspective. See also **Prichard, James Cowles (1786–1848)**.

Most important, however, was the elder De Candolle's apotheosis of a war in nature. Competitive struggle among individuals for space, water and other physical needs, and between groups of species for the occupancy of geographical areas–"war" as De Candolle memorably stated–was seen as the primary cause in determining the extent and shape of plant distribution. Charles Lyell brought the motif home to British readers in his *Principles of Geology* (1830–1833) with his talk of the "economy of nature" in which "foes" and "allies" undergo "continual strife" in order to "invade adjacent territories." See also **Lyell, Sir Charles (1797–1875)**.

Here were the foundations for separate biogeographical and ecological lines of thought. Joachim Schouw's work *Grundtraek til almindelig Plantegeographie* (1822), and Hewett Cottrell Watson's *Cybele Britannica* (1847–1860) were exemplary in this regard. The key to understanding why certain organisms appear under particular conditions, and in regular association with other organisms, was seen by them to lie in the organism's physiological requirements. Valuable studies of small-scale environmental phenomena increased in number. Large-scale biogeographical speculations proliferated too. Many geologists were interested in the evidence for former climatic conditions, and compared present-day botanical and zoological patterns with what might have been the case in the past. Charles Lyell's influential *Principles of Geology* included an important account of geographical distribution. Lyell codified the important notion of time: the idea that geological history played a crucial part in accounting for present-day patterns across the globe. "The extent of this parceling out of the globe," said Lyell in volume 2 of *Principles of Geology* "may be considered as one of the most interesting facts clearly established by the advance of modern science." Using Lyell's perspective, the British naturalist Edward Forbes showed how animals and plants must have streamed into Britain at different times in the geological past when the climate was warmer and the country was connected by dry land to continental Europe. Forbes' interpretation was particularly effective in explaining the existence of disjunct species (a single species living in two or more geographic locations separated by inhospitable terrain). He postulated that floras and faunas spread out as far as they could under suitable topographic and climatic conditions. If the conditions changed, and the flora and fauna retreated, some species might be left behind in small refuges. Hence, Forbes identified Iberian species in the far west of Cornwall and Ireland. His work served as a model for other similar studies. See also **Forbes, Edward (1815–1854)**; and **Paleoclimatology**.

Lyell's supporters, including Forbes, Darwin, Joseph Dalton Hooker and Alfred Russel Wallace, believed that these biogeographical patterns must also be connected with the history and origin of species. They pondered the changing patterns of animals and plants over the globe during geological time. The Harvard botanist Asa Gray analyzed the botanical connections between Japan and parts of North America, proposing that the species that lived on two landmasses, such as the magnolia, depended on former changes in climate and geological topography. One original flora had expanded and contracted as the climate and geographical connections changed, leaving a number of species behind. Joseph Hooker similarly analyzed the Antarctic flora in terms of landbridges that had allowed plants to expand their territories and which were subsequently separated. These men had first-hand knowledge of their materials. Hooker collected extensively in southern waters on James Ross's exploring expedition on the *Erebus* and *Terror*, 1838–1843. At this time, there was no notion of continental drift, and the continents were believed to have been relatively stable in position and outline. Nineteenth-century naturalists freely proposed the upheaval and removal of landbridges to account for biogeographical data. See also **Gray, Asa (1810–1888)**; and **Hooker, Joseph Dalton (1817–1911)**.

Nationalistic motifs fed smoothly into the debate. All the concerns of the newly emerging colonial powers in Europe and America were eminently suited to a number of botanical and zoological projects.

For example, scientific voyages played a highly significant role in nineteenth-century biogeographical science. First, the collection of natural history specimens from different parts of the globe was instrumental in many of the major transformations of biological thought that took place in the West. Charles Darwin's and Alfred Russel Wallace's evolutionary theory was based, in part, on biogeographical notions that emerged from their voyages. Elsewhere, contemporary classification schemes were stretched to breaking point to accommodate strange new species. New questions were asked about acclimatization and economic exploitation. Westerners' encounters with faraway groups of indigenous peoples encouraged scholars to contemplate the human race in all its geographic diversity. Even the act of traveling far away from their homelands gave naturalists a fresh perspective on the natural historical sciences of their day. Voyages of geographical and scientific discovery, in short, opened up the world to scholars and initiated the process of globalization that has come to characterize modern times. See also **Taxonomy (The History)**.

Second, land and sea voyages were a key element in the territorial and political expansion of European powers during the nineteenth century. Observational sciences of all kinds were perceived as an integral part of colonizing endeavor. In the age of expanding empires, scientific voyages explicitly manifested the overlay between science and the state. Traveling naturalists provided the information on which enlarged views about the geographical distribution of the natural world could be based.

Most significantly for the history of the biogeographical sciences, a demographic understanding of animal and plant distribution became commonplace in the eighteenth and nineteenth centuries. It can be seen in a commitment to the idea of the "nations" of animals and plants, an idea that was particularly encouraged by voyaging naturalists who made surveys of indigenous species. To analyze these "nations" naturalists used statistics just as if they were quantifying a human population and it can surely be no coincidence that British, French, American and German state

departments were compiling extensive civil statistics of overseas territories at the same time. Francis Buchanan's vast statistical report on the people and geography of Bengal ran in tandem with his work on the geographical distribution of plants and fish in India. Humboldt, Robert Brown and Augustin De Candolle made the technique of "botanical arithmetic" (the numerical proportion of species to genera, and other quantitative relationships) an essential part of such cataloguing enterprises. Numerical demographic techniques were used for describing foreign insect and bird distributions wherever possible. See also **Brown, Robert (1773–1858)**.

Moreover, naturalists used metaphors that drew on human demographic concepts like "state," "kingdom" and "province," and nationalistic expressions like "motherland," "outpost" and "station." Joseph Hooker included the category of "tramp" in a taxonomic work to account for the existence of European weeds in New Zealand. Significantly, however, the word most often used by European and American naturalists writing about animal and plant distribution in mid-century, was "colonist": any plant or animal successfully living beyond its usual limits was said to be a "colonist." This was the language of human expansionist power.

Maps–a key component of a traveler's equipment–were also essential for representing developing biogeographical concepts like the existence of regional floras and faunas. Maps and living boundary lines specially intrigued British naturalists. Lines were drawn on existing topographic maps to indicate the extent of known floras and faunas–an exercise that stimulated people to look for geographical features that restricted the spread of plants and animals. Barriers presented by mountain ranges, deserts and waterways were noted. Soon organisms were understood to possess an inherent, almost inexhaustible ability to expand their geographic range, in the same way that human beings had the power to increase in number and expand. The spread of individual species could be stopped only by topographical or (as we now would call it) ecological barriers.

Darwin, Wallace and Beyond

Contemplating and investigating these boundary lines, both on the global scale and at the level of local populations, played a central role in Darwin's and Wallace's thinking, stimulating both men independently to inquire into the reasons for the existing distribution patterns of animals and plants. During his *Beagle* expedition, 1831–1836, Darwin thought closely about the barriers impeding the natural, fecund spread of organisms westward and southward across South America; and about the unbreachable channels of water separating the inhabitants of the Galapagos Islands, an archipelago consisting of some 15 islets lying at a great distance from the coast of Ecuador. Darwin noted that the animal inhabitants of the islands, though very similar, were not identical. Similarly, while exploring the natural history of the Amazonian basin in 1848–1852, Wallace pondered geographic variants of birds and butterflies, noting how each distinct race lived in its own territory separated from others by the tributaries of the River Amazon. Both men envisaged an initial population spreading out over a region and then diversifying under the impetus of local conditions.

Later, in Malaysia in 1854–1862, Wallace codified his ideas about large-scale distribution patterns by mapping the point at which southern Pacific organisms met Indo-Asiatic organisms: the boundary, or dividing line, between two giant biogeographical provinces. This boundary was subsequently called Wallace's line. It is useful to note that Wallace was also deeply interested in the geographical distribution of the different ethnic groups among the islands of Malaysia and Indonesia, and that this too played an important role in his biogeographical ideas. See also **Wallace, Alfred Russel (1823–1913)**.

Neither of these men could have reached their independent conclusions about natural selection and evolutionary connections between species without thinking hard about the reasons for the distribution patterns that they saw. Competitive struggle among individuals for space, water and other physical needs, and between groups of animals or plants for territorial possession, reflected not only Augustin De Candolle's adage about biological "warfare" between species, but also the conceptual heart of British colonial thought. Their respective travels, in this sense, presented Darwin and Wallace with problems about the origins of species that could best be addressed through the motifs of colonial, expanding, industrialized Britain. While it is true that the theory of evolution by natural selection ultimately drew on a very wide range of biological and cultural factors, this initial push from Darwin's and Wallace's wish to understand animal and plant geography should not be underestimated.

Darwin's and Wallace's theory of evolution by natural selection provided a strong theoretical base for the nascent subjects of biogeography and ecology. Darwin believed animal and plant distribution strongly supported his arguments. In *On the Origin of Species or, the preservation of favored races in the struggle for life* (1859) he dedicated two chapters to explaining his views. He regarded distribution as good evidence for evolution by natural selection. He explained the existence of disjunct plant species by proposing that a flora had formerly spread over a wider area and subsequently retreated when climatic, geological or other factors intervened. He developed this scheme to suggest that there had formerly been a period when the tropics were considerably cooler and that several northern species must have crossed the Equator to colonize lands further south. These species were subsequently exposed to very different combinations of organic and environmental factors, which stimulated adaptation and change. Hence similar but not identical species ("representative" species) could be seen in the present-day northern and southern hemispheres, separated by the tropics.

Darwin also added considerably to nineteenth-century understanding of the means by which animals and plants were dispersed over the globe: the transport of seeds by birds, the possession of hooks and sticky attachments, the effects of wind, ocean currents and rivers, and the unwitting transport of organisms by mankind from country to country. Darwin believed organisms could spread much more widely than usually thought; and he opposed the belief held by his friends that landbridge connections may have allowed plants and animals to move between continents. Darwin rejected landbridges as an explanation for disjunct species. This position set him apart from most of his contemporaries. Alfred Wegener's work on continental drift in 1915 ultimately showed that Darwin was misguided in rejecting former continental connections as an explanation for disjunct distribution patterns. See also Continental Drift.

Long before then, Moritz Wagner heavily criticized Darwin for rejecting the role of geographical isolation in evolution. Even though Darwin in his early work said that speciation needed geographical isolation, as was obviously the case in the Galapagos Island fauna, he afterwards changed his mind and in the *Origin of Species* expressed his belief that most variation and adaptation would take place among large competitive populations. In *The Darwinian Theory and the Law of the Migration of Organisms* (1868), Wagner insisted on the need for a period of geographical isolation. Modern biologists still debate the degree that various isolating mechanisms, such as differences in courtship or breeding periods, are necessary for populations to diverge.

Wallace became a leading authority on zoological distribution. His *Geographical Distribution of Animals* (1876) provided a model for evolutionary naturalists studying biogeography. In it he followed P. L. Sclater's view that there were six main zoological provinces across the globe. These could be thought of as centers of evolution, which he named Palearctic, Necrotic, Indian (or Oriental), Ethiopian, Neotropical and Australian. E. L. Trouessart, the French geographer, added two more: the Arctic and Antarctic. Wallace saw Eurasia and North America as the greatest foci of adaptive change from which animals and plants migrated outwards. Less advanced forms were driven southwards by better adapted, more quickly evolving, dominant groups from the north. The existence of tapirs in South America and southeast Asia, for instance, was explicable by supposing they originated in the north and were pushed southwards in different directions as climate changed and other species evolved. Hooker also favored the view that Eurasia was the principal focus of plant evolution. In *Island Life* (1880), Wallace strongly disagreed with Darwin's proposals about a former cooling of the tropics, proposing instead that species may have hopped along mountain ranges from north to south rather as if the summits were oceanic islands.

This northern bias, while biologically and geographically accurate, also reflected common European and American beliefs in the cultural primacy of the developed nations. Darwin's and Wallace's theory directly endorsed the notion that northern species were more efficient, more competitive, and better adapted: humans as well as animals and plants. The idea of evolution, fortified by the developed world's growing technological and territorial power, appeared to justify, or account for, the sweeping aside of so-called "primitive" species, including "primitive" races of mankind. A small number of late-nineteenth-century thinkers did warn against the dangers of extinction and exploitation, but they were in a minority. Such men included George Perkins Marsh in the USA, who wrote his *Man and Nature* (1864) on the theme of the earth being torn apart by human greed. The majority, however, were not ready to abandon the belief that "civilized" humankind was intended to dominate the earth. It seemed to

them perfectly natural that well-adapted, competitive plants or animals might wipe out, or endanger, less successful indigenous organisms. Darwin and Hooker discussed the Tasmanian and New Zealand flora in precisely these terms. The indigenous plants were unfit, they said, and likely to be exterminated by more successful European colonizing species–and they drew an analogy with the near-extermination of Tasmanian aborigines and the low "moral" nature of Maoris. They assumed the innate superiority of European settlers. Late-nineteenth-century biogeography consequently reflected many of the jingoistic views of northern nations.

Darwin's and Wallace's illumination of the social relations between organisms are often said to form the intellectual basis of the emerging science of ecology. Yet the role of Darwinism in the origin of ecology is problematic. Certainly the concept of natural selection lost much of its foothold during the last decades of the century and does not appear to have directly influenced many early ecologists. See also **Ecology (The History)**.

Yet several botanists actively incorporated evolutionary biogeographical ideas into their work, frequently drawing on their travels and studies of indigenous overseas floras. Oscar Drude of the Dresden Botanic Gardens attempted to assess the structure of populations by ranking plants in categories from "social" to "scarce." Andreas Schimper studied plant physiology and environmental factors. Eugenius Warming, who trained as a plant physiologist, argued in *Plantesamfund* (1895) that physical factors primarily determined where a plant could live. He developed the concept of botanical communities, such as meadow-land, heath and birch forest. On virgin land, or on ground destroyed by fire, he suggested that communities succeeded each other in a regular sequence. His work, together with Schimper's *Pflanzengeographie auf physiologischer Grundlage* (1898), fused plant geography with plant physiology and marked the beginnings of modern studies in ecology. See also **Plant Sciences (The History)**.

Similarly, Darwin's and Wallace's influence can be seen in the way zoological attention turned to the biotic and abiotic features of the natural environment, to food chains and ecological balance. An explicit statement of the concept of what is now called a biotic community was made in Karl Mobius' study of oyster beds in 1877. The American naturalist Stephen Forbes described the interactions of species in freshwater lakes. In 1881 Karl Semper developed the idea of what became known as the food chain. Studies of seas and lakes contributed greatly to ideas about the functioning of communities. The marine biologist Victor Hensen led expeditions to Greenland and the tropics in 1889 during which he demonstrated that cold waters supported a greater variety of life. Hensen went on to establish a remarkable research school in Kiel in Germany, specializing in plankton studies and fisheries stocks. The United States government established a Fish Commission in 1871, headed by Spencer Baird, to inquire into the depletion of commercial fish stocks. Ten years later Baird equipped a vessel for survey work and played a part in the creation of the Woods Hole laboratory. While these developments were not strictly biogeographical in either scope or practice, they materially contributed to the advancement of biogeographical understanding of the oceans. See also **Ocean**.

BIOHERM. A geological term for beds or mounds of colonial and gregarious marine fossils with calcareous shells or skeletons. Present day bioherms are usually referred to as coral reefs.

BIOINORGANIC CHEMISTRY. Study of the mechanisms involved in the behavior of metal-containing molecules in living organisms, e.g., biological transport of iron, the effect of copper on nucleic acid and nucleoproteins, molybdenum, and manganese complexes, etc.

BIOLOGICAL ENERGY TRANSFER. When ionization occurs in a substance such as a protein, the net charge produced in the protein probably migrates throughout a large region of the molecule with various probabilities favoring its occurrence in one part of the molecule or another. Eventually, after approximately 10^{-14} seconds, the excess (or deficiency) of charge probably settles in an *s-s* bond or in the hydrogen atom attached to the carbon of the peptide bond which is opposite to one or other of the amino acid residues. Thus, regardless of the site of the original ionization in the molecule, there is considerable transfer of energy throughout a large portion of the molecule. However, the phrase *energy transfer* is generally meant to include those cases where it might occur in addition to this; for example, intermolecularly either between adjacent protein molecules or between protein and solvent molecules. It can also apply to excitation. See also *Active Transport* under **Cell (Biology)**.

BIOLOGICAL EQUILIBRIUM. The state of coordination that maintains an animal's normal posture.

Equilibrium of aquatic animals, such as fish, is maintained by the resistance of the surrounding water in relation to specialized body form, by muscular movements of body and fins, and by the gas-filled swim bladder. The bodies of most fishes are heavier above, as is shown by their floating back downward when dead, but the combination of these factors maintains their erect position.

Terrestrial animals maintain their posture by constant muscular adjustment in response to stimuli received by sensory organs in the sole of the feet and in the muscles and tendons. A portion of the inner ear of vertebrates is also a center of equilibrium. End organs in the semicircular canals of this organ are stimulated by movement in the liquid filling the canals when the animal moves. The three canals lie in the three planes of space so that at least one is activated by any movement. The results of their reaction are transmitted to one of the lower brain centers, whence the proper impulses are relayed to the muscles.

Equilibrium in flight demands very delicate coordination of essentially the same type. In insects and bats it is supposed to be accomplished partly through delicate sense organs located in the wings.

BIOLOGICAL LEVEL. Although there is no precise scale to express the level of an organism in terms of biological organization, a few terms are used roughly, to place organisms into levels, commencing at the lowest level (a bit of protoplasm surrounded by a membrane as typified by a protozoan), up through the multicellular animals, such as sponges, through the *tissue level* (evidence of differentiation of tissues in many-celled animals), through the *organ level* (animals with specific organs), and finally to the *organ-system level*, as represented by most complex animals. Thus, the term biological level is used in roughly classifying organisms in terms of complexity.

BIOLOGICAL RHYTHMS. Objects exposed to rhythmic influences typically exhibit variations of their measurable properties, with harmonic components rationally related to the driving period. The temperature of stone in the desert, e.g., rises and falls diurnally. In the absence of an external driving rhythm, objects also have their own spontaneous dynamics which may include rhythmic variations. For example, energy production in sugar-metabolizing yeast cells oscillates with a steady half-minute period. Any healthy mammal's heart beats spontaneously, requiring no external pacemaker; and during fibrillation (see also **Fibrillation**) each cm^2 area of its surface exhibits a 10-Hz electrical oscillation. Pacemaker activity in nerve cells is common and in some cases unaccountably precise. Organisms exposed to periodic influences adapt to them on the short time scale of individual physiology in ways little different in principle from a stone's response to changing solar irradiation: the heartbeat can be synchronized by an electronic pacemaker and sugar metabolism by periodic injections of any one of several metabolites. Populations of such

biological clocks, exposed to rhythmic influences from neighbors, tend to lock together in collective mutual entrainment: this happens among cells in the pacemaker node of the heart, among yeast cells suspended in water, and among individual fireflies blinking in tropical nights. On the longer time scale of evolution, it seems that organisms have also adapted genetically to the persistently reliable period of the Earth's rotation (and all that goes with it), by developing spontaneous internal "clocks" that have a remarkably reliable periodicity close to 24 hours; thus the adjective "circadian" ("roughly daily"). Their biochemical mechanisms are now reasonably well understood; they resemble the epigenetic oscillations observed on a shorter time scale in bacteria. But the adaptive value of their spontaneous cycling in an environment that already provides an equally reliable clock in the rising and setting of the sun remains somewhat mysterious. The physiology and dynamics of their entrainment to the cycle of light and dark is well understood. See also **Circadian Clock**; and **Jet-lag**. Some annual rhythms of animal and plant development appear to continue spontaneously with a period distinctly different from a year unless entrained to seasonal variations of day length and temperature.

BIOLOGY. The science of life. As with several of the fundamental sciences, over the last several decades, biology has been segmented into a number of fields of specialization. These include biochemistry, bioengineering, biomedicine, biophysics, cell biology, developmental biology, ecogenetics, evolutionary biology, marine biology, microbiology, and molecular biology, among others. Convenient umbrella terms sometimes used include the *biological sciences* and the *life sciences*.

There are hundreds of entries of varying length included throughout this encyclopedia that relate to the biological sciences. Many of these entries include lists of references for further reading.

BIOLUMINESCENCE. Many living organisms exhibit the unique property of producing visible light, a phenomenon referred to as bioluminescence. Known light-emitting organisms have either oxidative or peroxidative enzymes that couple the chemical energy released from the enzyme reaction to give electronic excitation of a luminescent compound. The compound that is oxidized with subsequent light emission is usually referred to as *luciferin* and the enzyme that catalyzes the reaction as *luciferase*. Most luciferins and luciferases that have been isolated from unrelated species are different in molecular structure. With one known exception, combinations of luciferin and luciferase from different species do not exhibit bioluminescence.

The light-producing reaction in a number of organisms can be represented simply by: $\text{Luciferin} + \text{O}_2 \xrightarrow{\textit{Lusiferase}} \text{Light}$. Some luminous organisms catalyzing this reaction are: (1) *Cypridina* (a crustacean); (2) *Apogon* (a fish), and (3) *Gonyaulax* (a protozoan). The latter organism is mainly responsible for the phosphorescence (so-called) of the sea.

In other instances, some luciferins must first undergo a luciferase-catalyzed activation reaction prior to their being catalytically oxidized by the enzyme to produce light. There are two well-known cases:

(1) The firefly:

$$\text{Luciferin} + \text{Adenosine Triphosphate (ATP)} \xrightarrow{\textit{Luciferase; } Mg^{2+}} \text{Activate Luciferin}$$

$$\text{Activated Luciferin} + \text{O}_2 \xrightarrow{\textit{Luciferase}} \text{Light}$$

(2) The sea pansy (*Renilla*):

$$\text{Luciferin} + 3',5'\text{-Diphosphoadenosine (DPA)} \xrightarrow{\textit{Luciferase; } Ca^{2+}} \text{Activate Luciferin}$$

$$\text{Activated Luciferin} + \text{O}_2 \xrightarrow{\textit{Luciferase}} \text{Light}$$

Both of these activation reactions are linked to adenine-containing nucleotides of great biological importance. Since the measurement of light can be made an extremely sensitive and rapid technique, the most sensitive and rapid assays known have been developed for ATP and DPA, using the foregoing luminescent systems. Nucleotide concentrations of less than 1×10^{-9} M are easily detectable using electronic instrumentation. Firefly luciferase-luciferin preparations for ATP assays are commercially available.

The structure of firefly luciferin has been confirmed by total synthesis. The firefly emits a yellow-green luminescence, and luciferin in this case is a benzthiazole derivative. Activation of the firefly luciferin involves the elimination of pyrophosphate from ATP with the formation of an acid anhydride linkage between the carboxyl group of luciferin and the phosphate group of adenylic acid forming luciferyl-adenylate.

All other systems that have been extensively studied emit light in the blue-green region of the spectrum. In these cases, the luciferins appear to be indole derivatives.

Some animals, such as the marine acorn worms (Balanoglossus), produce light via a peroxidation reaction and appear not to require molecular oxygen for luminescence. The luciferase in this case is a peroxidase of the classical type and catalyzes the reaction: $\text{Luciferin} + \text{H}_2\text{O}_2 \xrightarrow{\textit{Lusiferase}} \text{Light}$.

Commercially available horseradish peroxidase (crystalline) will substitute for luciferase in the foregoing reaction. In addition, a compound of known structure, 5-amino-2, 3-dihydro-1, 4-phthalazinedione (also known as *luminol*), will substitute for luciferin. The mechanisms appear to be the same regardless of the way in which the crosses are made. Thus, a model bioluminescent system is available and can be used as a sensitivity assay for H_2O_2 at neutral pH. The identification of luciferase as a peroxidase is of interest since this represents the only demonstration of a bioluminescent system in which the catalytic nature of a luciferase molecule has been defined.

Most of the luminescent systems mentioned appear to be under some nerve control. Normally, a luminous flash is observed after mechanical or electrical stimulation of most of the aforementioned species. A number of these also exhibit a diurnal rhythm of luminescence.

Among the lower forms of life, there are two well-known examples of luminescence which are not under nerve control, giving a continuous glow of visible light. These are the luminous bacteria, frequently found growing on dead fish, and luminous fungi, which grow abundantly on rotting wood. These cells apparently depend upon the oxidation of an organic molecule and hydrogen that is transferred through diphosphopyridine nucleotide (DPN; also termed NAD, nicotinamide adenine dinucleotide) and the enzyme system to drive the luminescent reaction. Known details of these luminescent reactions are represented as follows. For bacteria:

$$\text{DPNH} + \text{H}^+ + \text{Flavin Mononucleotide (FMN)} \underset{}{\overset{\textit{Oxidase}}{\rightleftharpoons}} \text{FMNH}_2 + \text{DPN}$$

$$\text{FMNH}_2 + \text{Long-chain Aliphatic Aldehyde} + \text{O}_2 \xrightarrow{\textit{Lusiferase}} \text{Light}$$

and for fungi

$$\text{DPNH} + \text{H}^+ + \text{Unknown Compound (X)} \overset{\textit{Oxidase}}{\rightleftharpoons} \text{XH}_2 + \text{DPN}$$

$$\text{XH}_2 + \text{O}_2 \xrightarrow{\textit{Lusiferase}} \text{Light}$$

Both of these systems are apparently closely linked to respiratory processes and in this sense are analogous to one another. Luciferase from a luminous bacterium, *Photobacterium fischeri*, has been made into-crystal in high yield.

See also **Luminescence**.

BIOMATERIALS, PROSTHETICS, AND BIOMEDICAL DEVICES. Prosthetics or biomedical devices are objects which serve as body replacement parts for humans and other animals or as tools for implantation of such parts. An implanted prosthetic or biomedical device is fabricated from a biomaterial and surgically inserted into the living body by a physician or other health care provider. Such implants are intended to function in the body for some period of time in order to perform a specific task. Medical devices may replace a damaged part of anatomy, e.g., total joint replacement; simulate a missing part, e.g., mammary prosthesis; correct a deformity, e.g., spinal plates; aid in tissue healing, e.g., burn dressings; rectify the mode of operation of a diseased organ, e.g., cardiac pacemakers; or aid in diagnosis, e.g., insulin electrodes.

Prosthetics and biomedical devices are composed of biocompatible materials, or biomaterials. In the early 1930s the only biomaterials were wood, glass, and metals. These were used mostly in surgical instruments, paracorporeal devices, and disposable products. The advent of synthetic polymers and biocompatible metals in the latter part of the twentieth century has changed the entire character of health care delivery. Polymers, metals, and ceramics originally designed for commercial applications have been adapted for prostheses, opening the way for implantable pacemakers, vascular grafts, diagnostic/therapeutic catheters, and a variety of other orthopedic devices. The term prosthesis encompases both external and internal devices.

Biomaterials

A biomaterial is defined as a systemic, pharmacologically inert substance designed for implantation or incorporation within the human body. A biomaterial must be mechanically adaptable for its designated function and have the required shear, stress, strain, Young's modulus, compliance, tensile strength, and temperature-related properties for the application. Moreover, biomaterials ideally should be nontoxic, i.e., neither teratogenic, carcinogenic, or mutagenic; nonimmunogenic; biocompatible; biodurable, unless designed as bioresorbable; sterilizable; readily available; and possess characteristics allowing easy fabrication. The traditional areas for biomaterials are plastic and reconstructive surgery, dentistry, and bone and tissue repair. A widening variety of materials are being used in these areas. Artificial organs play an important role in preventive medicine, especially in the early prevention of organ failure.

To be biocompatible is to interact with all tissues and organs of the body in a nontoxic manner, not destroying the cellular constituents of the body fluids with which the material interfaces. In some applications, interaction of an implant with the body is both desirable and necessary, as, for example, when a fibrous capsule forms and prevents implant movement.

Polymers, metals, ceramics, and glasses may be utilized as biomaterials. Polymers, an important class of biomaterials, vary greatly in structure and properties. The fundamental structure may be one of a carbon chain, e.g., in polyethylene or Teflon, or one having ester, ether, sulfide, or amide bond linkages. Polysilicones, having a −Si−O−Si− backbone, may contain no carbon.

Plastics are found in implants and components for reconstructive surgery, as components in medical instruments, equipment, packaging materials, and in a wide array of medical disposables. Plastics have assumed many of the roles once restricted to metals and ceramics.

Metals are used when mechanical strength or electrical conductivity is required of a device. For example, as of 1995 the femoral component of a hip replacement device was metal, as were the conductors of cardiac pacemaker leads. Titanium and titanium alloys are well tolerated in the body. This is partly the result of the strongly adhering oxide layer that forms over the metal surface, making the interface between the body and biomaterial effectively a ceramic rather than a metal. Titanium finds wide use as the femoral component of the artificial hip, where it exhibits great strength, comparatively light weight (the density of titanium is 4.5 g/cm^3), and excellent fatigue resistance. Another area in which titanium has replaced all other metals and alloys is as the casing material for cardiac pacemakers, neural stimulators, and implantable defibrillators.

Stainless steel alloys are also useful in orthopedic applications. Stainless steel alloys are used in the manufacture of staples, screws, pins, etc. These alloys are used primarily in applications requiring great tensile strength. Elgiloy, an interesting cobalt-based alloy, was originally developed for the mainspring of mechanical watches. This is used essentially as the conductor of neural stimulator leads, which require excellent flexibility and fatigue resistance. Nitinol, an unusual alloy of nickel and titanium, exhibits shape memory. Its main application has been in dentistry, where its resilience rather than its shape-memory characteristic is of value.

Ceramics include a large number of inorganic nonmetallic solids that feature high compressive strength and relative chemical inertness. Low temperature isotropic (LTI) carbon has excellent thromboresistance and has found use in heart valves and percutaneous connectors. LTI carbon, known as LTI, was originally developed for encapsulating nuclear reactor fuel. This material was adapted for biomedical applications in the 1970s. LTI is formed by pyrolysis of hydrocarbons at temperatures between 1000 and 2400 °C (1832 and 4352 °F). Aluminum oxide [CAS: 1344-28-1], Al_2O_3, forms the basis of dental implants. In the polycrystalline form this ceramic is suitable for load-bearing hip prostheses. See also **Ceramics**.

Bioglasses are surface-active ceramics that can induce a direct chemical bond between an implant and the surrounding tissue. One example is 45S5 bioglass, which consists of 45% SiO_2, 6% P_2O_5, 24.5% CaO, and 24.5% Na_2O. The various calcium phosphates have excellent compatibility with bone and are remodeled by the body when used for filling osseous defects.

Medical Devices

Medical devices are officially classified into one of three classes. Class I devices are general controls that are primarily intended as devices that pose no potential risk to health, and thus can be adequately regulated without imposing standards or the need for premarket review. Manufacturers of these devices must register with the United States Food and Drug Administration (FDA), provide a listing of products, maintain adequate reports, and comply with good manufacturing practices. Examples are stethoscopes, periodontic syringes, nebulizers, vaginal insufflators, etc.

Class II devices have performance standards and are applicable when general controls are not adequate to assure the safety and effectiveness of a device, based on the potential risk to health posed by the device. To classify a device in the Class II category, the FDA must find that enough data are available on which to base adequate performance standards that would control the safety and effectiveness of the device. Examples are diagnostic catheters, electrocardiographs, wound dressings, percutaneous catheters, gastrointestinal irrigation systems, etc.

Class III devices require premarket approval. When a device is critical, i.e., life-supporting and/or life-sustaining, unless adequate justification is given for classifying it in another category, it is a Class III device. Class III also contains devices after 1976 that are not sufficiently similar to pre-1976 devices, and devices that were regulated as new drugs before 1976. Examples are bronchial tubes, ventilators, vascular grafts, pacemakers, cardiopulmonary bypass, surgical meshes, etc. See also **Cardiovascular Devices**.

Bioresorbable Polymers

Biomaterials scientists have worked diligently to synthesize polymeric structures which exhibit biocompatibility and long-term biostability. Devices made from these polymers are intended to be implanted in the body for years, and in some cases decades.

The concept of using biodegradable materials for implants which serve a temporary function is a relatively new one. This concept has gained acceptance as it has been realized that an implanted material does not

have to be inert, but can be degraded and/or metabolized *in vivo* once its function has been accomplished. Resorbable polymers have been utilized successfully in the manufacture of sutures, small bone fixation devices, and drug delivery systems.

Several groups have experimented with bioresorbable polymers that have a predictable degree of bioresorbability when exposed to the physiological environment. By the judicious choice of bioresorbability rate it is hoped that as the polymer is resorbed it will leave surface voids where natural tissue would grow, resulting in autologous organ regeneration. The temporary nature of the device will impart initial mechanical functionality to the implant, but after time will be resorbed as the natural tissue regenerates. This concept has been experimentally applied to the regeneration of tissue such as in the liver, skeletal tissue, cartilage, and the vascular wall.

One area in which predictable biodegradation is used is the area of degradable surgical sutures. An incision wound, when held together with sutures, heals to about 80% of initial strength within four weeks. Surgical suture is one of the earliest clinical implants in recorded history. Catgut suture, obtained from ovine or bovine intestinal submucosa, was known in 150 AD in the time of Galen, who built his reputation by treating wounded gladiators.

Catgut is infection-resistant. The biodegradation of catgut results in elimination of foreign material that otherwise could serve as a nidus for infection or, in the urinary tract, calcification. As a result, chromic catgut, which uses chromic acid as a cross-linking agent, is still preferred in some procedures. Chromic catgut is considered by some to be the most suitable suture material for vaginal hysterectomy owing to its extensibility and rapid absorption. Treatment of natural catgut with synthetic polymers exemplifies the merging of old and new technology. Coating catgut with a polyurethane resin allows catgut to retain its initial tensile strength longer.

The first synthetic polyglycolic acid suture was introduced in 1970 with great success. This is because synthetic polymers are preferable to natural polymers since greater control over uniformity and mechanical properties are obtainable. The foreign body response to synthetic polymer absorption generally is quite predictable whereas catgut absorption is variable and usually produces a more intense inflammatory reaction. This greater tissue compatibility is crucial when the implant must serve as an inert, mechanical device prior to bioresorption.

Polylactic Acid. Polylactic acid [CAS: 26100-51-6] (PLA) was introduced in 1966 for degradable surgical implants. Hydrolysis yields lactic acid, a normal intermediate of carbohydrate metabolism. Polyglycolic acid sutures have a predictable degradation rate which coincides with the healing sequence of natural tissues.

Polylactic acid, also known as polylactide, is prepared from the cyclic diester of lactic acid (lactide) by ring-opening addition polymerization.

Pure DL-lactide displays greater bioresorbability, whereas pure poly-L-lactide is more hydrolytically resistant.

The actual time required for poly-L-lactide implants to be completely absorbed is relatively long, and depends on polymer purity, processing conditions, implant site, and physical dimensions of the implant.

Polyglycolic Acid. Polyglycolic acid [CAS: 26009-03-0] (PGA), also known as polyglycolide, was first reported in 1893, but it was not until 1967 that the first commercially successful patent was granted for sutures. Like polylactide, polyglycolide is synthesized from the cyclic diester.

An important difference between polylactide and polyglycolide, is that polyglycolide (mp 220 °C (428 °F) is higher melting than poly-L-lactide (mp 170 °C (338 °F). Although the polymerization reaction in both cases is reversible at high temperature, melt processing of polyglycolide is more difficult because the melting temperature is close to its decomposition temperature.

Unlike poly-L-lactide which is absorbed slowly, polyglycolide is absorbed within a few months post-implantation owing to greater hydrolytic susceptibility. *In vitro* experiments have shown the effect on degradation by enzymes, pH, annealing treatments, and gamma irradiation. Braided polyglycolide sutures undergo surprisingly rapid hydrolysis *in vivo* owing to cellular enzymes released during the acute inflammatory response following implantation.

Low humidity ethylene oxide gas sterilization procedures and moisture-proof packaging for polyglycolic acid products are necessary because of the susceptibility to degradation resulting from exposure to moisture and gamma sterilization.

Poly(Lactide-co-Glycolide). Mixtures of lactide and glycolide monomers have been copolymerized in an effort to extend the range of polymer properties and rates of *in vivo* absorption. Poly(lactide-*co*-glycolide) polymers undergo a simple hydrolysis degradation mechanism, which is sensitive to both pH and the presence of enzymes.

A 90% glycolide, 10% L-lactide copolymer was the first successful clinical material of this type. Braided absorbable suture made from this copolymer is similar to pure polyglycolide suture. Both were absorbed between 90 and 120 days post-implantation but the copolymer retained strength slightly longer and was absorbed sooner than polyglycolide. These differences in absorption rate result from differences in polymer morphology. The amorphous regions of poly(lactide-*co*-glycolide) are more susceptible to hydrolytic attack than the crystalline regions.

An amorphous poly(L-lactide-*co*-glycolide) copolymer is used in surgical clips and staples. The preferred composition chosen for manufacture of clips and staples is the 70/30 L-lactide/glycolide copolymer.

Polydioxanone. Fibers made from polymers containing a high percentage of polyglycolide are considered too stiff for monofilament suture and thus are available only in braided form above the microsuture size range. The first clinically tested monofilament synthetic absorbable suture was made from polydioxanone.

Polydioxanone (PDS) is completely eliminated from the body upon absorption. The mechanism of polydioxanone degradation is similar to that observed for other synthetic bioabsorbable polymers. Polydioxanone degradation *in vitro* was affected by gamma irradiation dosage but not substantially by the presence of enzymes. The strength loss and absorption of braided PDS, but not monofilament PDS, implanted in infected wounds, however, was significantly greater than in noninfected wounds.

Other biomedical applications for polydioxanone include its use in orthopedics, plastic surgery, drug delivery, cardiovascular applications, and tissue engineering applications.

Poly(Ethylene Oxide)–Poly(Ethylene Terephthalate) Copolymers. The poly(ethylene oxide)–poly(ethylene terephthalate) (PEO/PET) copolymers were first described in 1954. This group of polymers was developed in an attempt to simultaneously reduce the crystallinity of PET, and increase its hydrophilicity to improve dyeability. PEO/PET copolymers with increased PEO contents produce surfaces that approach zero interfacial energy between the implant and the adjacent biological tissue. The collagenous capsule formed around the implant is thinner as the PEO contents increase.

A family of PEO/PET copolymers has been synthesized and the characterized structures found to be close to those expected in theory. A wide degradation envelope has been achieved by adjusting the PEO-to-PET ratio. Mechanical properties prove useful for medical applications, and the 60/40 PEO/PET composition is reported as optimal.

Poly(Glycolide-co-Trimethylene Carbonate). Another successful approach to obtaining an absorbable polymer capable of producing flexible monofilaments has involved finding a new type of monomer for copolymerization with glycolide. In order to achieve the desired fiber properties, the two monomers were copolymerized so the final product was a block copolymer of the ABA type, where A was pure polyglycolide and B, a random copolymer of mostly poly(trimethylene carbonate). The selected composition was about 30–40% poly(trimethylene carbonate). This suture reportedly has excellent flexibility and superior *in vivo* tensile strength retention compared to polyglycolide. It has been absorbed without adverse reaction in about seven months. Metabolism studies show that the route of excretion for the trimethylene carbonate moiety is somewhat different from the glycolate moiety. Most of the glycolate is excreted by urine whereas most of the carbonate is excreted by expired CO_2 and urine.

Poly(Ethylene Carbonate). Like polyesters, polycarbonates are bioabsorbable only if the hydrolyzable linkages are accessible to enzymes and/or water molecules. Thus pellets of poly(ethylene carbonate) $-\!\left(\!-\mathrm{OCOOCH_2CH_2}-\right)_n-$ weighing 200 mg implanted in the peritoneal cavity of rats, were bioabsorbed in only two weeks, whereas similar pellets of poly(propylene carbonate) $-\!\left(\!-\mathrm{OCOOCH(CH_3)CH_2}-\right)_n-$ showed no evidence of bioabsorption after two months. Because poly(ethylene carbonate) hydrolyzes more rapidly *in vivo* than *in vitro*, enzyme-catalyzed hydrolysis is postulated as a contributing factor in polymer absorption. Copolymers of polyethylene and polypropylene carbonate have been developed as an approach to achieving the desired physical and pharmacological properties of microsphere drug delivery systems.

Polycaprolactone. Polycaprolactone is absorbed very slowly *in vivo*, releasing ε-hydroxycaproic acid as the sole metabolite. Degradation occurs

in two phases: nonenzymatic bulk hydrolysis of ester linkages followed by fragmentation, and release of oligomeric species. Polycaprolactone fragments ultimately are degraded in the phagosomes of macrophages and giant cells, a process that involves lysosome-derived enzymes. *In vitro*, polycaprolactone degradation is enhanced by microbial and enzymatic activity. Predictably, amorphous regions of the polymer are degraded prior to breakdown of the crystalline regions.

Copolymers of ε-caprolactone and glycolide have been evaluated in fiber form as potential absorbable sutures. Strong, flexible monofilaments have been produced which maintain 11–37% of initial tensile strength after two weeks *in vivo*.

Poly(Ester–Amides). Another approach to obtaining improvements in the properties of synthetic absorbable polymers is the synthesis of polymers containing both ester and amide linkages. The rationale for designing poly(ester–amide) materials is to combine the absorbability of polyesters with the high performance of polyamides. Two types have been reported.

Poly(Orthoesters). The degradation of a bioresorbable polymer occurs in four stages: hydration, loss of strength, loss of integrity, and loss of mass. This typical behavior limits most of the previously mentioned polymers for use as matrices for slow release drug delivery implants because incorporated drugs that are water soluble have been found simply to leach out at a first-order rate. Thus bioabsorbable polymers which are extremely hydrophobic have been developed to prevent hydration yet still possess hydrolytically unstable linkages. This results in degradation of polymer on the exposed surfaces only thereby releasing the drug content at a more uniform rate. Such polymers have been termed bioerodible.

Poly(orthoesters) represent the first class of bioerodible polymers designed specifically for drug delivery applications.

Poly(Anhydrides). Poly(anhydrides) are another class of synthetic polymers used for bioerodible matrix, drug delivery implant experiments. Degradation of these polymers simply releases the dicarboxylic acid monomers. Preliminary toxicological evaluations showed that the polymers and degradation products had acceptable biocompatibility and did not exhibit cytotoxicity or mutagenicity.

Shape Memory Alloys

TiNi shape memory alloy (SMA) has attracted much attention for biomedical applications such as implants (bone plate and marrow needle) and for surgical and dental instruments, devices and fixtures, such as orthodontic fixtures and biopsy forceps. See also **Shape-Memory Alloys**. This is due to its excellent biocompatibility and mechanical characteristics. Research on biomedical applications of SMA was started in the 1970s with animal experiments initially, followed by clinical tests. The first example of successful biomedical and dental applications of SMA are available and many new applications are being developed.

SMAs' properties which led to their wide acceptance in biomedical applications include biocompatibility, superelasticity, shape memory effect, hysteresis, and fatigue resistance. Studies show that TiNi has superior corrosion resistance, due to the formation of a passive titanium-oxide layer (TiO_2) similar to that found on Ti alloys. This oxide layer increases the stability of the surface layers by protecting the bulk material from corrosion and creates a physical and chemical barrier against Ni oxidation.

The shape memory effect has been utilized also for actuator functions in medical applications as a urethral valve and artificial sphincter.

Superelasticity. SMAs exhibit superelasticity when they are in the austenite phase. Figure 1 shows the typical superelastic stress–strain curve (solid line) compared with the stress–strain curve of stainless steel (dashed line). An important feature of superelastic materials is that they exhibit constant loading and unloading stesses over a wide range of strain.

As shown in Figure 1, the effective strain range $\Sigma_{\text{eff}}(TN)$ of TiNi corresponding to an optimal force zone is much larger than $\Sigma_{\text{eff}}(SS)$ of stainless steel. Hence, a superelastic device can provide a constant pressing force even if the pressed part recedes by a limited amount during the installed period. On the contrary, the pressing force of the appliance made from stainless steel will drop drastically if the pressed part deforms, so that the performance will deteriorate. An orthodontic arch wire was the first product to take advantage of this property. This characteristic is put into use in superelastic eyeglass frames. These eyeglass frames have become very popular in the United States, Europe and Japan, and are available in almost every optician's store. These frames can be twisted a full 180°, but more importantly the frames press against the head with a constant and

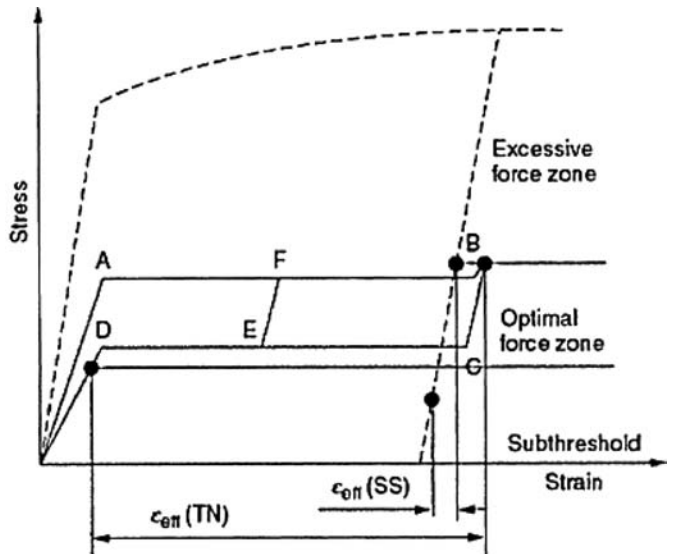

Fig. 1. Typical stress–strain curve of superelastic materials and stainless steel. The superelastic materials exhibit constant unloading stress over a wide range of strain.

comfortable stress. not only is "fit" less important, but small bends and twists that may develop do not cause discomfort to the wearer.

The superelasticity of SMAs makes it easy to depoly SMA stents. Stents made from stainless steel are expanded against the vessel wall by plastic deformation caused by the inflation of a balloon placed inside the stent. TiNi stents, on the other hand, are self-expanding.

Anti-Kinking Properties. The stress of stainless steel remains nearly constant in the plastic region (see Figure 1). This means that a small increase of stress in the plastic region could lead to a drasticincrease of strain or the failure of the medical appliance made from stainless steel. On the other hand, the stiffness of superelastic TiNi increases drastically after point B at the end of the loading plateau. The increase in stiffness would prevent the local strain in the high strain areas from further increasing and cause the strain to be partitioned in the areas of lower strain. Hence, strain localization is prevented by creating a more uniform strain than could not be realized with a conventional material.

Applications: Orthopedic (Marrow Needles). Figures 2 and 3 show two types of marrow needles, which are used in the repair of a broken thighbone. When the Kunster marrow needle of stainless steel is used, the blood flow inside the bone can be blocked and recovery can be delayed. It also has the drawback of low torsional strength. On the other hand, a Kunster marrow needle of SMA can be inserted into the bone in its initial straight shape and turned to curved shape by heating as shown in Figure 2.

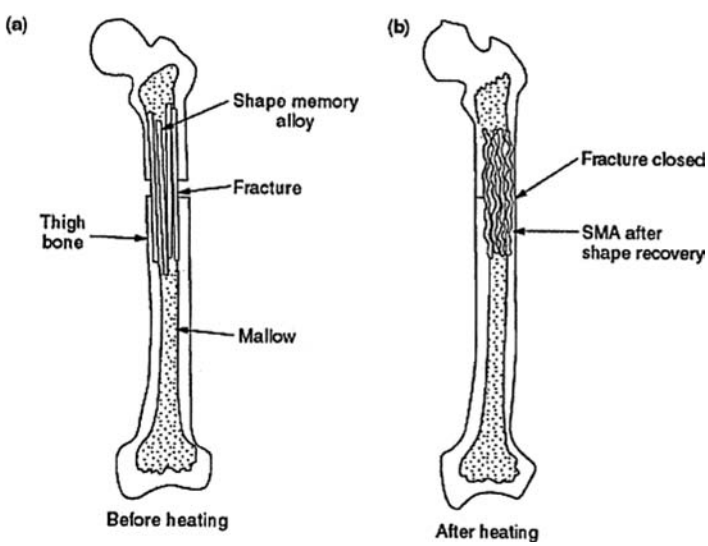

Fig. 2. Kunster marrow needle.

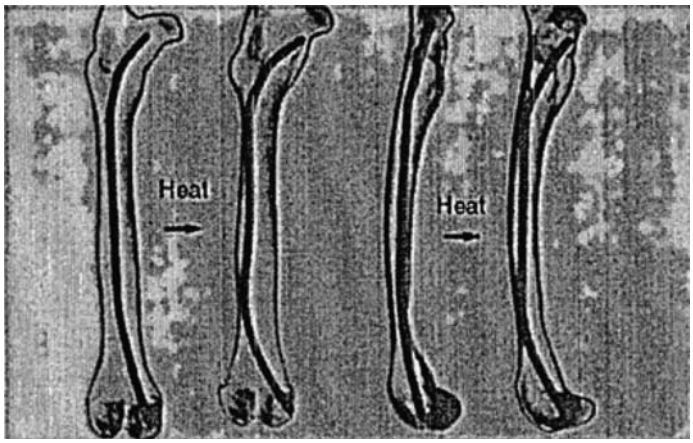

Fig. 3. Marrow needles before and after heating.

The kunstar marrow needle shown in Figure 3 has a complicated shape for the purpose of reinforcement, which makes it difficult to insert the needle in the broken bone. Using the shape memory effect, insertion can be greatly improved as shown in the figure, without loosing the reinforcing function, because the needles can be inserted in a simpler shape and the necessary size and shape are recovered by heating he needle in the marrow.

Currently available joint prostheses are made of bone cement to be fixed in the bone. Stress acting on the joint prosthesis is quite intense and severe; three to six times the body weight of the patient under nominal action and under such stress being cycled up to 10^6 times. Conventional bone cement causes several inconveniences: gradual loosening after implantation and resultant infection and other complications. The prosthetic joint made of TiNi SMA was developed to avoid such problems. High wear resistance is also another advantage of the TiNi prosthetic joint.

Bone Staple and Bone Plate. Bone staple and bone plate are used to fix broken bones. A bone staple made of SMA can be inserted at low temperature in holes opened in the bone and then heated by the body temperature to recover its original shape to provide a compressive force in the surfaces of the broken bone. Bone plates are attached with screws for fixing broken bones. Bone plates made of TiNi SMA are more effective in connecting the broken bones than the bone plates made of conventional material because the SMA bone plates can provide compressive force on the fracture surface of the broken bones as well as a repair. Healing proceeds faster under uniform compressive force. See also **Orthopedic Devices**.

Dental Applications. Owing to its superelasticity, TiNi has found many applications in dentistry. It is obvious that superelasticity presents the orthodontists with better mechanical characteristics as compared to the conventional elastic materials such as stainless. When fixtures made of conventional elastic material such as stainless steel are used, the reforming force drops and the fixture loosens with the movement of the teeth. Hence, the fixture must be replaced several times before the treatment is finished. When SMA fixture is used, it can maintain a constant reforming force in a wide range of teeth movement owing its superelasticity so that no future replacement is required after the initial installation. Clinical results show also a faster movement of the teeth and a shorter chair time as compared with stainless steel wire.

Among the methods for restoring the mastication funtion of patients missing more than one tooth, a teeth-root prosthesis is considered to be the method that creates the most natural mastication function.

The key to partial denture is the development of an attachment used for connecting the partial denture with the retained teeth for which clasps have been conventionally used. One of the drawbacks of clasps made of conventional elastic materials is loosening during use; this can be improved by replacing the elastic materials with a superelastic TiNi alloy. Another drawback of clasps is of esthetic nature, since they are visible with the teeth alignment. In order to overcome this problem the size of the attachment must be smaller than the width of the teeth so that it can be embedded in the teeth completely. A precision attachment using a small screw has recently become available, but they have to be designed and fabricated very precisely so that they lack the flexibility to follow the change in the setting condition due to the shape change of the jawbone during long-term use. Because of its flexibility, using an attachment made of SMA can solve this problem. The SMA attachment consists of two parts: the fixed part, which is made of a conventional dental porcelain-fusible cast alloy and attached to the full cast crown on the anchor teeth, and the movable part, which is made of TiNi SMA and fixed onthe side of the partial denture.

Surgical Instruments. Since superelastic tubing became available in the early to mid 1990s, a variety of catheter products and other endovascular devices using TiNi have appeared on the market. Early applications of TiNi are retrieval baskets with TiNi kink-resistant shafts, as well as a superelastic basket to retrieve stones from kidneys, bladders, bile ducts, etc. An interesting example is the interaortic balloon pump (IABP) used in cardiac assist procedures. The use of NiTi has allowed reduction in the size of the device compared with the polymer tube based designs, and increased the flexibility and kink resistance compared with stainless steel tube designs.

Biopsy forceps made from stainless steel are very delicate instruments that can be destroyed by even very slight mishandling. TiNi instruments, on the other hand, can handle considerable bending without buckling, kinking or permanent deformation.

Stent. The term stent is used for devices that are used to scaffold or brace the inside circumference of tubular passages or lumens, such as the esophagus bilary duct, and most importantly, a host of blood vessels including coronary, carotid, iliac, arota and femoral arteries. Stenting in the cardiovascular system is most often used as a follow-up to balloon angioplasty, a procedure in which a balloon is placed in the diseased vessel and expanded in order to reopen a clogged lumen. Ballooning provides immediate improvement in blood flow, but 30% of the patients have restenosed within a year and need further treatment. The placement of a stent immediately after angioplasty has been shown to significantly decrease the propensity for restenosis. Stents are also used to support grafts, e.g., in the treatment of aneurysms.

Most stents today are stainless steel and are expanded against a vessel wall by plastic deformation caused by the inflation of a balloon placed inside the stent. TiNi stents, on the other hand, are self-expanding. They are shape-set to the open configuration, compressed into a catheter, then pushed out of the catheter and allowed to expand against a vessel wall. Typically, the manufactured stent outer diameter is about 10% greater than the vessel in order to assure that the stent anchors firmly in place. The flexibility of TiNi is about 10–20 times greater thanthe stainless steel and can bear as high as 10% reversible strain. The NiTi stenta are made of knitted or welded wire, laser cut or photoetched sheet, and laser cut tubing. The preferred devices are laser cut tubing avoiding overlaps and welds.

BIOME. Over the earth, there are certain relatively distinct combinations of climatic conditions, life forms, and essential geologic and hydrologic features that, when taken together, form large geographic regions within which there persists a reasonably stable balance between the various natural forces and features present. Admittedly, the definition of a biome is inexact because the parameters of a biome are less than precise. Another definition of biome is that it is a climax community that characterizes a particular natural region. In ecological terms, climax refers to that final stable stage of development that a community, species, flora, or fauna attains in a given environment. Thus, the major world climaxes correspond to formations and biomes, a formation being defined as a group of associations that exist together as a result of their closely similar life pattern, habits, and climatic requirements.

Biomes do not recognize political divisions or continental divisions, nor are their boundaries sharp, often one biome blending in with another over an extensive area. A biome, unlike a mountain range, lake, or course of a river is not measured with the precision of geodesy because it possesses fuzzy, sometimes undulating borders that generally, if illustrated on a map, will at best have wide and blended borders. In actuality, the biome is a convenient tool devised by natural scientists to map and classify what otherwise would remain blurred phenomena. And, in these respects, the concept of the biome is helpful.

The borders of biomes do correspond with geographical borders where a given biome interfaces with an ocean, the latter also considered a biome.

Land biomes include (1) the deserts, (2) tundra, (3) grassland, (4) savanna, (5) chaparral, (6) woodland, (7) coniferous forest, (8) deciduous forest, and (9) tropical forest — arranged here in order of increasing amounts of vegetation. At least two interfacing areas with the oceans are also recognized, i.e., (10) the reefs and (11) the rocky shores, which obviously are natural forms which do not satisfy the characterization of any of the aforementioned nine land biomes.

The Desert Biomes. Although the various desert biomes of the earth display considerable variation, generally, a desert may be defined as "an area of low moisture due to low rainfall, i.e., less than ten inches annually, with high evaporation or extreme cold, and which supports only specialized vegetation, not that typical of the latitudes in which it is located, and is generally unsuitable for human habitation under natural conditions. Deserts are not characterized by uniformity of elevation, but wind often produces distinctive erosion features, e.g., dunes" (*American Geological Institute*).

It is estimated that deserts occupy approximately one-fifth of the earth's land surface. The principal deserts lie between 35°N and 35°S of the equator. These are regions covered by anticyclonic belts and high pressures, thus combining with other factors to result in low rainfall. See **Atmosphere (Earth)**; and **Winds and Air Movement**. The major desert biomes are depicted in the aforementioned figure. It is interesting to note that the major tropical forests of the earth are also located between the same aforementioned parallels of latitude, but generally considerably closer to the equator.

With reference to Fig. 1 starting with the Western hemisphere, the Mojave desert of southern California is the largest in North America, with an area of approximately 13,500 square miles (34,965 square kilometers). Essentially continuous, with interspersed semidesert areas, the Vizcaino desert, located in Baja California, Mexico has an area of about 6000 square miles (15,540 square kilometers). Directly south of Arizona on the Mexican mainland are semidesert areas and the Grande desert in Sonora with an area of some 2500 square miles (6475 square kilometers). Also identified as formal desert areas in the United States are the Great Salt Lake desert, located in northwestern Utah, with an area of about 4000 square miles (10,360 square kilometers), the Painted Desert, located in northeastern Arizona, with an area of approximately 5000 square miles (12,950 square kilometers); the Colorado-Southeastern California desert, with an area of some 4000 square miles (10,360 square kilometers); the High desert, located in central Oregon, with an area of 3000 square miles (7770 square kilometers); and the smaller Black Rock desert (600 square miles; 1554 square kilometers) and Smoke Creek desert (300 square miles; 777 square kilometers), located in northwestern Nevada.

Located in South America are the Sechura Desert, situated in northwestern Peru, with an area of about 10,000 square miles (25,900 square kilometers) the Atacama Desert, located in northern Chile, with an area of about 70,000 square miles (181,300 square kilometers); and the Patagonian desert of Argentina, with an estimated area of over 300,000 square miles (777,000 square kilometers).

In Africa, the Sahara, covering well over 3.5 million square miles (9 million square kilometers), represents about 32% of the total land area of that continent and spreads over parts of several African nations. Over 20% of the Sahara is located in Libya and this portion (some 650,000 miles; 1,683,500 square kilometers) is sometimes referred to as the Libyan desert. The Nubian portion of the Sahara occupies about 100,000 square miles (259,000 square kilometers). The Kalahari Desert, of some 200,000 square miles (518,000 square kilometers), is located in South West Africa. It is interesting to note that the Nile River valley and environs separates the Sahara from the other desert areas of northeastern Africa and that these areas are interrupted only by the Red Sea which lies just west of the desert regions of the Arabian peninsula. Thus, with these exceptions, there is essentially continuous desert from west to east over a distance of some 5000 lineal miles (8045 kilometers).

The great desert areas of the Middle East include: the Arabian Desert of the Arabian Peninsula, which has an area of about 500,000 square

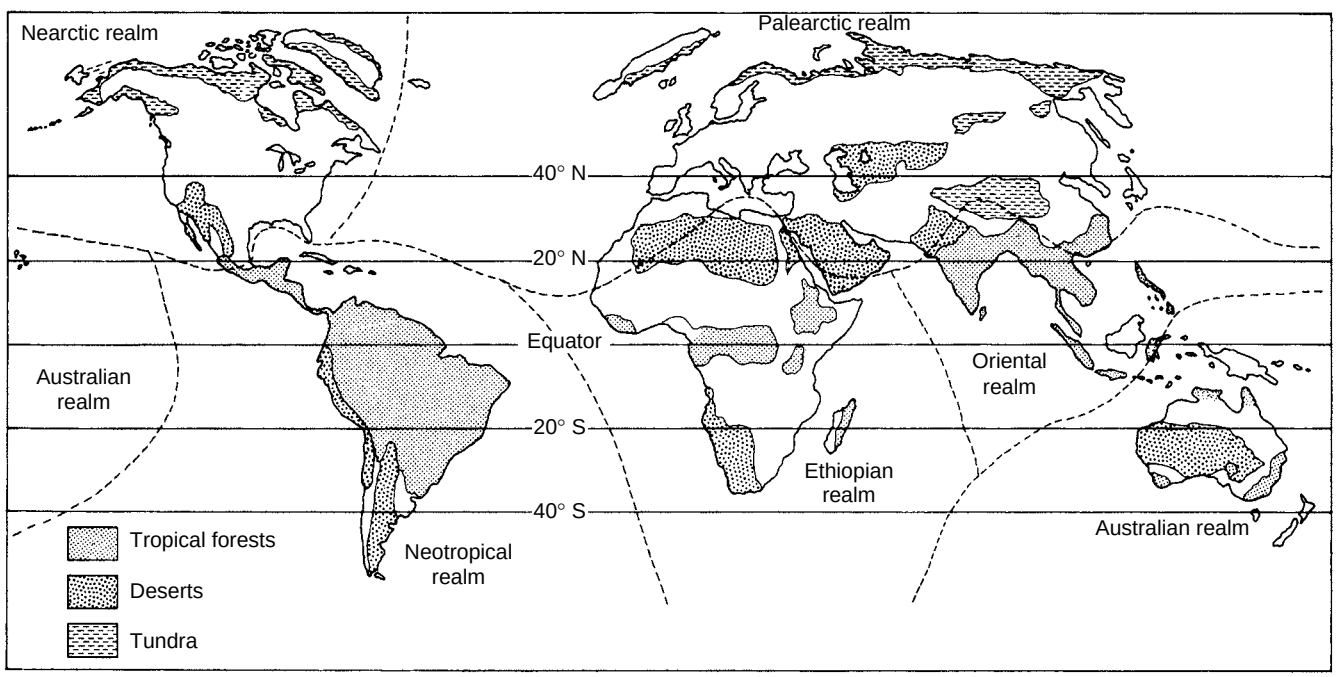

Fig. 1. Major realms of the earth as originally proposed by A.R. Wallace.

miles (1,295,000 square kilometers); the Rub al Khali Desert, with an area of about 250,000 square miles (647,500 square kilometers), located in southeastern Saudi Arabia; the Syrian Desert, with an area of about 125,000 square miles (323,750 square kilometers), located in the northern part of the Arabian peninsula; the Nefud Desert, located in the northern and central parts of Saudi Arabia, with an estimated area of 50,000 square miles (129,500 square kilometers); the Dasht-i-Lut Desert of eastern Iran, with an area of approximately 20,000 square miles (51,800 square kilometers); and the Dasht-i-Kavir desert, located in north central Iran, with an area of about 18,000 square miles (46,620 square kilometers).

The Gobi Desert, located in southern Mongolia, is the largest desert in Asia, with an estimated area of about 400,000 square miles (1,036,000 square kilometers). The Taklamakan Desert of southern Sinkiang province (People's Republic of China) is estimated to cover an area of 125,000 square miles (323,750 square kilometers). The Thar or Indian Desert, located in northwestern India has an area of about 100,000 square miles 259,000 square kilometers). The Kyzyl-Kum Desert of central Turkestan (Russia) has an area of about 90,000 square miles (233,100 square kilometers); the Kara Kum Desert of southern Turkestan has an estimated area of 105,000 square miles (271,950 square kilometers); and the Peski Muyun-Kum Desert of eastern Turkestan, an area of about 17,000 square miles (44,030 square kilometers).

The Australian desert is estimated to cover about 600,000 square miles; 1,554,000 square kilometers; (the total land area of Australia is 2,974,580 square miles; 7,704,162 square kilometers). Portions of the Australian desert with formal designations include: the Great Sandy Desert (northwestern Australia), 160,000 square miles (414,400 square kilometers); the Great Victoria Desert (southwestern), 125,000 square miles (323,750 square kilometers); the Arunta Desert (central), 120,000 square miles (310,800 square kilometers); and the Gibson Desert (western), 85,000 square miles (220,150 square kilometers).

Although long periods of time may elapse between rainfalls, no desert is known that is completely dry. In an exceptional rainy season, for example, parts of the Sahara may have as many as 11 days of rainfall. Most desert areas are characterized by wide temperature spans between day and night, sometimes ranging over a difference of 60 °F (16 °C). During the course of a year, the Gobi desert will have a variation of nearly 120 degrees. Located north of most other desert areas of the earth, the Gobi has extremely cold winter temperatures, persisting at 5 °F (−15 °C) (daytime) for many days and dropping at night to −30 °F (−34 °C).

Because of such wide temperature changes over such short periods, violent winds develop in many desert regions. Some desert winds have special names: for example, the *simoon*, a very hot and dry wind, which blows over the Sahara and Arabian deserts during spring and summer; the *harmattan*, which carries desert air toward the Gulf of Guinea (west Africa); and the *khamsin*, which blows over Egypt for many days during March, April, and May. The winds form and remove sand dunes; the terrain does not remain static. See also **Dune**.

Rivers disappear when a desert is formed. Old riverbeds are filled with sand. The dry beds of old river systems are known as *wadis*. Normally, the desert base immediately sucks up rainfall, but in cases of rare downpours, the wadis fill temporarily and flow violently, thus creating a hazard in the more developed areas where connecting roads have been built across desert regions. Rarely the deep waters in some desert areas are brought to the surface, such locations being known as oases. See also "Hydrology of Semiarid Areas" under entry on **Hydrology**.

The desert areas of North America support small animals, including jack rabbits, kangaroo rats, cactus mice, pocket mice, cottontails, and rock and ground squirrels. Some of these desert regions are well known for the beautiful spring flowering of desert annuals. Plants usually found in parts of these regions include Joshua trees, various cacti, the saguaro, and various low shrubs, notably creosote bush and sagebrush.

The desert regions of southern Asia in some parts may support thorny bushes, sometimes called camel sage, small clumps of wiry grass, and low-profile sagebrush. Trees occasionally found include the tamarisk, cottonwood, zag, and turai. Animals found include jerboas, sand rats, moles, hedgehogs, eagles, owls, and hawks.

The desert areas of South America are largely windswept and thus there is a very sparse covering, if any, of such plants as cacti, yucca, sagebrush, agave, cereus, creosote bush, and bunch grass. These areas support some animals, including the rhea, armadillos, guanaco, vulture, fox, and the Patagonian "hare" (tuco tuco).

The plant life of the African deserts is very scant with exception of the infrequent oases. The latter are known for their date palms. Occasional desert plants include Welwitschia, euphorbias, including plants with tuberous roots. Animals found in some areas include porcupine, gundi, rock hyrax, lizards, tenrec, springbok, and eagles.

Saltbush and bluebush are found in the Australian deserts, as well as some eucalyptus, river red gum, and acacia trees. Among animals found are spiny devil lizards, rats, mice, marsupial moles, and parakeets.

Tundra. "A treeless, level or gently undulating plain characteristic of arctic and subarctic regions. It usually has a marshy surface which supports the growth of mosses, lichens, and numerous low shrubs and is underlain by a dark, mucky soil and permafrost." (*American Geological Institute*) Permafrost may be defined as any soil, subsoil, or other deposit, or even bedrock, occurring in arctic or subarctic regions at a variable depth beneath the earth's surface, in which a temperature below freezing has existed continuously for a long time (from two years to tens of thousands of years). This definition is based exclusively on temperature, and disregards the texture, degree of compaction, water content, and lithologic character of the material. Its thickness ranges from over 3000 feet (914 meters) in the north to about 1 foot (0.3 meter) in the southern perimeter of a permafrost area. Permafrost underlies about one-fifth of the land area of the earth.

The regions of tundra are indicated in accompanying figure. These regions support low forms of vegetation, including mosses, sedges, scattered herbs, lichens, and stunted shrubs. Animals of the tundra include the wolf, weasel, arctic fox, arctic hare, lemming, caribou, musk ox, arctic ground squirrel, polar bear, snowy owl, and ptarmigan.

Tropical Forest. Regions of tropical forest of the earth are shown in the accompanying figure. With a plentiful supply of rainfall and warmth, the tropical forests are lushly abundant with vegetation, which, in turn, assists in supporting a great variety of birds, insects, and other life forms. There are several types of tropical forests. Where a region is continuously warm and humid, as in lowlands found, for example, in the center of Africa, certain parts of India, and in the southeastern portions of Australia and Asia, even broad-leaved trees remain green throughout the year because, in essence, the growing season does not stop for periodic breaks. Some of these trees include the ebony, mahogany, and teak. Such regions are termed *rain forests*. In other regions, because there are very sharp breaks between the dry and rainy seasons, trees will shed their leaves in systematic fashion. Because of this parallel with the patterns in temperate zones, these regions are sometimes called *winter forests*. As a tropical forest may at its outer edges begin to blend with grasslands and less-favored areas climatically, the species found in the tropical forest may follow watercourses for long distances into the grasslands. These winding, long strips of forest are sometimes called *gallery forests*. Distinctive of the tropical forests are abundant rainfall, reliable rainfall (absence of unpredictable, long dry spells), and abundant and uniform light energy (the days and nights are about equally long summer and winter). Of particular interest is the vertical layering of these forests. This represents, in essence, a struggle by the various plant species for available light. Animal communities are also divided along vertical layers. The tall trees at the very top spread a thick canopy of leaves and, with intervening vertical levels of vegetation, extremely little of the incident sunshine reaches the floor of the forest (sometimes referred to as jungle). The light at the forest floor has been likened to a kind of twilight. In a rain forest that has been left undisturbed, i.e., tall trees have not been cut down so as to dilute the effect of the covering canopy, the base of the forest is quite unlike the popular conception of a jungle. The scant light reaching the forest floor will not support twisting and tangling undergrowth — the forest floor is relatively open and clean. Fallen tree limbs and leaves are quickly consumed by insects. The rain forest displays numerous unusual and extremely interesting trees, many species of which are described in this volume. See listing under entry on **Tree**.

About half of South America is covered with tropical forests where numerous species of lichens, orchids, mosses, bromeliads, tree ferns, bamboo, lianas, cabbage palms, and numerous other forms can be found. Tree snakes, parrots, and hummingbirds are found in abundance. Other animal forms include monkeys, anteaters, coati, sloth, paca, small deer, agouti, and kinkajou. In the tropical forests of Southeast Asia, some of the trees commonly found include teak, banyan, ebony, and Manila hemp. Bamboo is abundant. There are some 700 kinds of bamboo, ranging from types that grow only a few inches tall to other types that attain a height of 120 feet (36.6 meters) or more. In the forests of China, some species may

grow as much as 3 feet (0.9 meter) within a 24-hour period. Animals found in the tropical forests of India and Southeast Asia include the porcupine, rhinoceros, tiger, sun bear, sloth bear, antelope, and deer — with monkeys, gibbons, and orangutans in abundance. A wide variety of lizards is found, as well as many species of pheasants and poisonous snakes.

The tropical forests of New Guinea and of relatively small areas of Australia (as compared with the vast desert regions of that continent) are of two general types — the closed-canopy rain forest; or open eucalyptus forests, where mountain ash and stunted gum trees also are found. The animal life is interesting and abundant, including numerous marsupials — kangaroos, wallabies, koala — and opossums, the Tasmanian devil, platypus, and flying foxes.

Grasslands. In this class of biome, there is what might be termed a natural mid-form between the desert and other more richly vegetated biomes. Grasslands occur where there is inadequate rainfall and moisture to support trees, but sufficient moisture to support various kinds of grasses. The specific type of grassland mirrors the rainfall that it receives. Much of the middle portion of the United States and of Canada, in more or less of a strip north of the desert regions of the South, is or was grassland. Some authorities place North American grasslands into three categories: (1) *true prairie*, which supports blue stem and Indian grasses; (2) *short-grass plains*, where grama and buffalo grasses are found; and (3) the bunch-grass prairie. In these grasslands will be found jackrabbit, prairie dog, badger, fox, coyote, pocket gopher, pronghorn, and bison. Rattlesnakes and blue racers are prevalent.

There are large expanses of grasslands found on the other continents — the pampas of Argentina, and the great plains of southeastern Europe and Asia, sometimes termed steppes. A large portion of the former grasslands of the earth have disappeared as the result of agricultural and livestock pursuits.

Savannas. Also classified as a biome is the savanna, which may be defined as an open, grassy, essentially treeless plain, especially as found in tropical or subtropical regions. They usually are characterized by distinct wet and dry seasons. The trees and shrubs found in these areas are drought-resistant. Savannas are most prevalent in Africa and parts of Australia. A savanna has been described as being intermediate between a steppe and a forest. The savanna generally has a grassy bottom with what might be termed a sprinkling of plants and trees, but rather consistently having the aura of open country. The savannas of Africa typify what one might term the big-game landscape. Aside from the large deserts, the savanna is the most prevalent type of biome on the African continent. The typical rainfall pattern is a period of hard, soaking rain for a few months, followed by little or no rain for several months. Trees found in the African savannas include the acacia, baobab, euphorbia, and doom palm. The reasons for the formation and the continuing existence of savannas are not fully understood. Some authorities do not believe that the savanna, like the other land biomes, is essentially climate-created, but rather that the savanna can be attributed to other factors as well as climate. Factors may extend back to the primitive people who practiced shifting agriculture in these areas; or there may be peculiarities of the soil yet not fully understood; or the grazing of native ungulate herds may be a factor. Typical of grazing animals found in the African savannas are zebras, elands, gemsbok, hartebeests, and gnus. Also found are giraffes, bush elephant, ostrich, black and white rhinoceroses, lion, wart hog, cheetah, Cape hunting dog, ground squirrels, and golden mole.

The open savanna forests on the fringes of the interior of Australia account for about 24% of the land area of the continent. Trees found in these areas include the eucalyptus, jarrah, wallum, iron-bark, red stringybark, yellow box, coolibah, and white box. Among animal life are found the red kangaroo, emu, bandicoots, wombats, cockatoos, and parrots.

Woodland and Chaparral. These types of regions can be conveniently combined as one biome. The trees found in such regions include piñon-juniper, and stands of leathery-leaved trees, such as the manzanita and chamiso. Chaparral is defined as a thicket of shrubs, and thorny bushes. In terms of fauna, these regions support few distinctive animals, but rather some animals migrate in and out from other biomes. Regions of this type are found in central and southeastern Mexico, in Europe and Africa on either side of the Mediterranean and in the southwestern United States, notably in the hills and mountains of southern California where chaparral in long dry seasons always poses a serious fire threat.

Deciduous Forest. As implied by the name, this biome is the result of climatic and other factors which favor the growth of deciduous trees (shed their leaves in the fall), of which, of course, there are scores of species, such as the beeches, oaks, basswood, elms, and maples. Roughly, the entire eastern half of the United States was originally deciduous forest, as well as southeastern Canada and pockets in Canada as far west as the Rocky Mountains. These natural forests support numerous flowering herbs, and animals commonly found include opossum, short-tailed shrew, mice, chipmunk, white-tailed deer, red fox, black bear, moles, raccoon, and gray and fox squirrels.

Other extensive regions of deciduous forests are found in the United Kingdom, the southern portions of Scandinavia, and in a broad band extending from northern Spain through France, Belgium, the Netherlands, Germany, Czechoslovakia, Poland, and the Caucasus. Large deciduous forests are also found in several parts of the People's Republic of China (east central), in Japan and in Korea. Deciduous forests in South America essentially are limited to Chile.

Coniferous Forest. This biome is characterized by the great predominance of needle-leaf trees, such as pine and spruce. Coniferous forests are found throughout much of Canada, from coast to coast, and along a very wide strip paralleling the west coast of the United States north of San Francisco and continuing northwestward through Alaska. These forests also predominate in northern Eurasia from Scandinavia eastward across the former U.S.S.R. to the Bering Sea.

Realms

Closely associated with the concept of biomes is that of the realms. The concept of zoogeographic realms dates back to the early work of A.R. Wallace, who considered the earth as divided into six land realms whose boundaries were essentially fixed by impassable barriers by virtue of climate and topology. Over the years, some shifting of these boundaries has occurred, but Wallace's realms persist as the accepted biogeographical divisions of the earth. These realms are depicted in Fig. 1.

See also **Climate**; **Global Change**; and **Zoogeography (also called Chorology)**. Also check Alphabetical Index for such topics as biological diversity, air and water pollution, and climate.

BIOMIMETIC CHEMISTRY. An interdisciplinary approach to biochemistry including both organic and inorganic aspects of this field. The term means imitation or mimicry of natural organic processes in living systems, and encompasses such subjects as enzyme systems, vitamin B_{12} and flavins, oxygen binding and activation, bioorganic mechanisms, and nitrogen and small-molecule fixation. The technique was utilized in the synthesis of the bleomycin molecule. A notable example of biomimetic chemistry is the development of model synthetic catalysts that imitate the action of natural enzymes. The behavior of chymotrypsin has been duplicated by a manufactured catalyst that can accelerate certain reaction rates by the incredible factor of 100 billion.

BIONICS. The study of systems, particularly electronic systems, which function after the manner of, or in a manner characteristic of, or resembling, living systems.

BIOPAK. A container for housing a living organism in a habitable environment and for recording biological functions during space flight.

BIOPOLAR PATTERN. A lightning pattern revealed in cloud-to-ground lightning locations in which areas of predominantly negative flash locations are separated horizontally from positive flash locations. See also **Lightning**. This pattern has been identified in midlatitude mesoscale convective systems (MCSs). The convective regions of the MCSs (those with radar echoes greater than 35 dBZ) typically have negative lightning flashes, whereas the positive flashes are typically located in the stratiform region ($<$35 dBZ) adjacent to the convective region. The bipolar pattern is hypothesized to arise from 1) the advection of positively charged particles from the upper portions of the convective region to the stratiform region due to vertical wind shear; 2) *in situ* charging of ice particles that acquire positive charge in an environment of supercooled liquid water and mesoscale ascent in the stratiform cloud layer; or 3) some combination of the two processes.

BIOPOLYMERS. Biopolymers are the naturally occurring macromolecular materials that are the components of all living systems. There are three principal categories of biopolymers, proteins; nucleic acids; and polysaccharides. See also **Carbohydrates**; **Nucleic Acids**; and **Protein**. Biopolymers are formed through condensation of monomeric units; i.e., the corresponding monomers are amino acids, nucleotides, and monosaccharides for proteins, nucleic acids, and polysaccharides, respectively. The term biopolymers is also used to describe synthetic polymers prepared from the same or similar monomer units as are the natural molecules. See also **Amino Acids**.

In addition to being necessary for all forms of life, biopolymers, especially enzymes (proteins), have found commercial applications in various analytical techniques. See also **Biosensors**. In synthetic processes (see also **Enzymes in Organic Synthesis**); and in prescribed therapies (See also **Enzyme Therapeutic**; and **Vitamin**). Other naturally occurring biopolymers having significant commercial importance are the cellulose derivatives, e.g., cotton and wood, which are complex polysaccharides.

Analytical Techniques

Analytical techniques that utilize biopolymers, i.e., natural macromolecules such as proteins, nucleic acids, and polysaccharides that compose living substances, represent a rapidly expanding field. The number of applications is large and thus uses herein are limited to chiral chromatography, immunology, and biosensors.

Biopolymers have had a tremendous impact on the separation of nonsuperimposable, mirror-image isomers known as enantiomers. Enantiomers have identical physical and chemical properties in an achiral environment except that they rotate the plane of polarized light in opposite directions. Thus separation of enantiomers by chromatographic techniques presents special problems. Direct chiral resolution by liquid chromatography (lc) involves diastereomeric interactions between the chiral solute and the chiral stationary phase. See also **Liquid Chromatography**. Because biopolymers are chiral molecules and can form diastereomeric interactions with chiral solutes, they are ideal for use as chiral stationary phases. This property has led to a rapid growth of chromatographic stationary phases utilizing biopolymers to separate chiral molecules. They include cyclodextrin chromatographic phases, α_1-acid glycoprotein chromatographic phases, bovine serum albumin chromatographic phases, and cellulose triacetate and cellulose derivatives.

Biopolymers are employed in many immunological techniques, including the analysis of food, clinical samples, pesticides, and in other areas of analytical chemistry. Immunoassays are specific, sensitive, relatively easy to perform, and usually inexpensive. For repetitive analyses, immunoassays compare very favorably with many conventional methods in terms of both sensitivity and limits of detection. See also **Pesticide**.

One condition that must be met for the application of an immunochemical method is that the analyte must be capable of stimulating an immune response leading to the formation of antibodies in the immunized animal. These antibodies can then be isolated and used as highly specific analytical reagents (immunoassays). Analytes that can combine with the corresponding antibodies are called antigens. There are physical and chemical restrictions on the types of analytes that may be used as immunoassay antigens. In general, large, rigid, chemically complex molecules make good antigens. For example, serum albumin, mol wt ca 60,000, is a good antigen because of its large size, complex structure, and good structural stability. Large repeating polymers such as lipids and carbohydrates, make poor antigens as a result of the simplicity of

their structure, even though they may have high molecular weights and good structural stability. One molecule having mol wt 750, the smallest molecular mass that has demonstrated antigenic behavior, is *p*-azobenzenearsonatetrityrosine.

Antibodies are proteins, found in many body fluids such as tears, saliva, and urine, that are present in highest concentrations in blood serum. Because antibodies are proteins, they may be characterized by such physical properties as solubility, electrostatic charge, isoelectric point, and molecular weight. The particular proteins which exhibit antibody activity are the immunoglobulins (Ig). The principal immunoglobulin in blood serum is immunoglobulin G (IgG), the structure of which is similar to the other immunoglobins. See also **Antibody**.

There are estimated to be approximately 10 million potential combinations of antigen-binding specificities resulting from light-and heavy-chain combinations in the immunoglobulins. The possibility of utilizing all of these combinations as reagents in immunochemical methods is highly interesting though improbable.

Selectivity is an important consideration in analytical chemistry. Biologically derived polymers can be used as highly selective immobilized reagents in analytical applications. The first reported use of immobilized biopolymers as biosensors for the detection of an analyte was made in 1962. See also **Biosensors**. Since that first reported use there has been a great deal of development and application of immobilized biopolymers in analytical chemistry.

The immobilized enzyme electrode is the most common immobilized biopolymer sensor, consisting of a thin layer of enzyme immobilized on the surface of an electrochemical sensor. The enzyme catalyzes a reaction that converts the target substrate into a product that is detected electrochemically. The advantages of immobilized enzyme electrodes include minimal pretreatment of the sample matrix, small sample volume, and the recovery of the enzyme for repeated use. Several reviews and books have been published on immobilized enzyme electrodes.

Enzyme immunosensors are enzyme immunoassays coupled with electrochemical sensors. These sensors require multiple steps for analyte determination, and either sandwich assays or competitive binding assays may be used. Both of these assays use antibodies for the analyte of interest attached to a membrane on the surface of an electrochemical sensor.

BIOPROCESS ENGINEERING (Biotechnology). Biotechnology is the application of biological systems to the manufacture of products ranging from food-grade sweeteners and fuel alcohol to recombinant proteins for treatment of heart disease and cancer. The application of biotechnology also encompasses the use of chemicals to modify the behavior of biological systems, the genetic modification of organisms to confer new traits, and the science by which foreign DNA may be inserted into people to compensate for genes whose absence cause life-threatening conditions. Bioprocess engineering, the subject of this article, translates biotechnology into unit operations, biochemical processes, equipment and facilities for manufacturing bioproducts.

An array of engineering fundamentals is required to translate the discoveries of biotechnology into tangible commercial products, thereby putting biotechnology to work. This article presents the principles of the life sciences and engineering, the practice of key biotechnology manufacturing techniques, and the economic characteristics of the industries and manufacturing processes that encompass:

(1) Production of human and animal health-care products, food products, biologically active proteins, and chemicals.
(2) Design and scale-up of bioreactors to generate large quantities of transformed microbes or cells and the products which they generate.
(3) Separation and purification of biological molecules.

The principles and practice of bioprocess engineering are based in the biological sciences. The key technologies based on the biosciences are

(1) Identification of genes, and the products which result from them, for purposes of disease prevention, remediation, and development of new medicines.
(2) Application of molecular biology to obtain transformed microorganisms, cells, or animals having new and/or enhanced capabilities to generate bioproducts.
(3) Development of biological sensors coupled to microprocessors or computers for process control and monitoring of biological systems (including humans).

The pioneers of the biotechnology industry had a grasp not only of the science, but also an understanding of the financial aspects of taking a new technology from test tube to market in less than seven years. In the late 1970s and early 1980s, the technical success of the insulin project, and the apparent availability of venture capital for risky enterprises, converged to promote the industry. Venture capital was available in part due to government policy that promoted limited partnerships and relieved taxes on capital gains, although the laws have since changed. Some of the pioneers also had a sense that the large scale production, clinical testing, obtaining government regulatory approval, and marketing, required the infrastructure of a large pharmaceutical company. The first recombinant product approved by the FDA, human insulin, resulted from the cooperation of the biotechnology company, Genentech, and the pharmaceutical company, Eli Lilly. Genentech ultimately merged with another major international pharmaceutical company, Hoffmann-LaRoche, in 1990 (see timeline in Table 1).

Although the industry grew rapidly, profits were slow in coming. This is not surprising, given the seven to ten year time required to bring a new product to market. Financial success for some of the companies has occurred as the twenty-fifth birthday of the new biotechnology field is approached. Some companies have consolidated when faced with large costs of clinical trials, regulatory approval, and marketing of biotechnology derived products. In the meantime, the realization has grown that there are other products amenable to bioprocessing approaches. These products include polypeptides (animal growth hormones), amino acids, enzymes, and food products. As the price categories and profit margins of the products decrease, there is an increased need for bioprocess engineering to design efficient and cost-effective production systems.

New Biotechnology

The directed manipulation of genes distinguishes the new biotechnology from prior biotechnology. Biotechnology was broadly defined in 1991 by the U.S. Congress as "any technique that uses living organisms (or parts of organisms) to make or modify products, to improve plants or animals, or to develop microorganisms for specific uses" (OTA). This technology was probably first applied about 8000 years ago in the making of bread. Over the last 60 years it has helped to catalyze the growth of the pharmaceutical, food, agricultural-processing and specialty-product sectors of the U.S. economy to the point where sales exceed $100 billion/year.

A new sector of the biotechnology industry has grown significantly in economic importance since about 1990. It is sometimes referred to as the "new" biotechnology which represents a technology for manipulating genetic information and manufacturing products that are of biological origin or which affect biological activity. It is based on methods, introduced since 1970, and applied on an industrial scale since 1979, that enable directed manipulation of the cell's genetic machinery through recombinant DNA techniques. Recombinant DNA is defined by a "DNA molecule formed *in vitro* by ligating DNA molecules that are not normally joined "(see Walker and Cox)." A recombinant technique is a method "that helps to generate new combinations of genes that were originally present" in different organisms.

The new biotechnology, which occurred only recently on the timeline of bioprocessing, enables production of mammalian or plant proteins and other biomolecules having therapeutic value in quantities required for practical use (see Table 1). Recombinant methodologies also have potential for dramatically improving production efficiency of products already derived by fermentation through the directed modification of cellular metabolism, i.e., metabolic engineering. As summarized in the preface of a 1992 National Research Council Report, "scientists and engineers can now change the genetic make-up of microbial, plant, and animal cells to confer new characteristics. Biological molecules, for which there is no other means of industrial production, can now be generated. Existing industrial organisms can be systematically altered (i.e., engineered) to

TABLE 1. TIME-LINE OF MAJOR DEVELOPMENTS IN THE BIOTECHNOLOGY INDUSTRIES[a]

Date	Event
6000 B.C.	Bread making (involves yeast fermentation).
3000 B.C.	Moldy soybean curd used to treat skin infections in China.
2500 B.C.	Malting of barley, fermentation of beer in Egypt.
1857 A.D.	Pasteur proved yeasts are living cells that cause alcohol fermentation.
	Birth of microbiology.
1877	Pasteur and Joubert discovered some bacteria can kill anthrax bacilli.
1896	Gosio discovered mycophenolic acid; an antibacterial substance produced by microbes (too toxic for use as antibiotic).
1902	*Bacillus thuringiensis* first isolated from silk worm culture by Ishiwata.
1908	Ikeda identified MSG as flavor enhancer in Konbu.
	Invertase absorbed onto charcoal, i.e., first example of immobilized enzyme.
1909	Ajinimoto (Japan) initiates commercial production of sodium glutamate from wheat gluten and soybean hydrolysates.
1900–1920	Ethanol, glycerol, acetone, and butanol produced by fermentation.
1922	Banting and Best treated human with insulin obtained from animal pancreatic extractions.
1923	Citric acid fermentation plant using *Aspergillus niger* by Charles Pfizer.
1928	Alexander Fleming discovered penicillin from *Penicillum notatum*.
1943	Submerged culture of *P. chrysogenum* opened way for large-scale production of penicillin.
1945	Production through fermentation process scaled up to make enough penicillin to treat 100,000 patients per year.
	Beginning of rapid development of antibiotic industry. During World War II, research driven by 85% tax on "excess" profits, encouraged investment in research and development of antibiotics this led to their postwar growth.
1953	DNA structure and function elucidated.
	Xylose isomerase discovered.
1957	Commercial production of natural (L) amino acids via fermentation facilitated the discovery of *Micrococcus glutamicus* (later renamed *Corynebacterium glutamicum*).
	Glucose isomerizing capability of xylose isomerase reported.
1960	Lysine produced on a technical scale.
1961	First commercial production of MSG via fermentation.
1965	Corn bran and hull replaced xylose as inducer of glucose (xylose) isomerase in *Streptomyces phaeochromogenius*.
	Phenyl methyl ester of aspartic acid and phenylalanine (Aspartame) synthesized at G.D. Searle Co.
1967	Clinton Corn Processing ships first enzymatically produced fructose syrup.
1970	Smith et al., reported restriction endonuclease from *Haemophilis influenzae* that recognizes specific DNA target sequences.
1971	Cetus founded.
1973	Cohen and Boyer reported genetic engineering technique (EcoRI enzyme).
	Aspartase in immobilized *E. coli* cells catalyzes L-aspartic acid production from fumurate and ammonia.
1973–1974	Oil price increase (Yom Kippur war).
	HFCS market about $500–600 \times 10^6$ lb/yr in U.S. sugar price peaked at 30/lb.
1975	Kohler and Milstein reported monoclonal antibodies.
	Basic patent coverage for xylose (glucose) isomerase lost in lawsuit; opened up development of new HFCS processes.
1976	Genentech, Inc. was founded in by venture capitalist Robert A. Swanson and biochemist Dr. Herbert W. Boyer. In the early 1970s, Boyer and geneticist Stanley Cohen pioneered a new scientific field called recombinant DNA technology.
1977	Genentech, Inc., reported the production of the first human protein manufactured in a bacteria: somatostatin, a human growth hormone-releasing inhibitory factor. For the first time, a synthetic, recombinant gene was used to clone a protein. Many consider this to be the advent of the Age of Biotechnology.
	Sixteen bills introduced in Congress to regulate recombinant DNA research. The bills called for the development of bacteria and plasmids that could be prevented from escaping the laboratory environment. None of these bills passed.
	Bill Rutter and Howard Goodman isolated the gene for rat insulin.
	Walter Gilbert and Allan Maxam at Harvard University devised a method for sequencing DNA using chemicals rather than enzymes.
1978	Genentech, Inc. and The City of Hope National Medical Center announced the successful laboratory production of human insulin using recombinant DNA technology.
	Harvard researchers used genetic engineering techniques to produce rat insulin.
	Studies by David Botstein and others found that when a restrictive enzyme is applied to DNA from different individuals, the resulting sets of fragments sometimes differ markedly from one person to the next. Such variations in DNA are called restriction fragment length polymorphisms, or RFLPs, and they are extremely useful in genetic studies.
	William J. Rutter's laboratory at UCSF cloned a coat protein of the virus that causes hepatitis B.
	Biogen formed, developed interferons.
	Eli Lilly licensed recombinant insulin technology from Genetech.
	3.5×10^9 lb HFCS produced in U.S.
1979	John Baxter reported cloning the gene for human growth hormone.
	Another major oil price increase (OPEC). Sugar price at 12/lb.
	Energy saving method for drying ethanol using corn (starch) and cellulose based adsorbents reported.
1980	The U.S. Supreme Court ruled in that genetically altered life forms can be patented a Supreme Court decision in 1980 allowed the Exxon oil company to patent an oil-eating microorganism. This ruling opened up enormous possibilities for commercially exploiting genetic engineering.
	Researchers successfully introduced a human gene-one that codes for the protein interferon-into a bacterium.
	Kary Mullis and others at Cetus Corporation in Berkeley, California, invented a technique for multiplying DNA sequences *in vitro* by, the polymerase chain reaction (PCR). PCR has been called the most revolutionary new technique in molecular biology in the 1980s. Cetus patented the process, and in the summer of 1991 sold the patent to Hoffmann-La Roche, Inc. for $300 million.
	Amgen founded.
1981	Genentech, Inc. cloned interferon gamma.
	Bill Rutter and Pablo Valenzuela published a report in Nature on a yeast expression system to produce the hepatitis B surface antigen.
	Scientists at Ohio University produced the first transgenic animals by transferring genes from other animals into mice.
	Mary Harper and two colleagues mapped the gene for insulin. Mapping by in situ hybridization became a standard method.
	Hoechst AG, a West German chemical company, gave Massachusetts General Hospital, a teaching facility of Harvard Medical School, $\$70 \times 10^6$ to build a new Department of Molecular Biology in return for exclusive rights to any patent licenses that might emerge from the facility.

(*continued*)

TABLE 1. (*Continued*)

Date	Event
	Congressman Al Gore held a series of hearings on the relationship between academia and commercialization in the arena of biomedical research. He focused on the effect that the potential for huge profits from intellectual property and patent rights could have on the research environment at universities. Jonathan King, a professor at MIT speaking at the Gore hearings, reminded the biotech industry that "the most important long-term goal of biomedical research is to discover the causes of disease in order to prevent disease."
	AIDS cases identified and reported in San Francisco.
	Aspartame approved for food use by FDA.
	Chiron founded.
	Gene synthesizing machines developed.
	Sugar price at 30/lb.
1982	Genentech, Inc. received approval from the Food and Drug Administration to market genetically engineered human insulin. 1982 The U.S. Food and Drug Administration approves the first genetically engineered drug, a form of human insulin produced by bacteria.
	Applied Biosystems, Inc. introduced the first commercial gas phase protein sequencer, dramatically reducing the amount of protein sample needed for sequencing.
	Lindow requested government permission to test genetically engineered bacteria to control frost damage to potatoes and strawberries.
	Michael Smith at the University of British Columbia, Vancouver, developed a procedure for making precise amino acid changes anywhere in a protein.
	First transgenic mouse, rat gene transferred to mouse.
1983	Eli Lilly received a license to make insulin.
	Syntex Corporation received FDA approval for a monoclonal antibody-based diagnostic test for Chlamydia trachomatis.
	Stanford Research Institute International filed for a patent for an *E. coli* expression vector.
	Jay Levy's laboratory at UCSF isolated the AIDS virus at almost the same moment it was isolated at the Pasteur Institute in Paris and at the NIH.
	U.S. patents were granted to companies genetically engineering plants.
	A study of an extended family in Venezuela with Huntington's chorea demonstrated that family members with the disease show a distinct and characteristic pattern of restriction fragment lengths, leading to a new screening test. The same methods of investigation revealed patterns for cystic fibrosis, adult polycystic kidney disease, Duchenne muscular dystrophy, and others.
	Marvin Carruthers at the University of Colorado devised a method to construct fragments of DNA of predetermined sequence from five to about 75 base pairs long. He and Leroy Hood at the California Institute of Technology invented instruments that could make such fragments automatically.
	Aspartame came on market sold by G.D. Searle as Nutrasweet®.
	Worldwide antibiotic sales at about $8 billion.
	First product sales of recombinant insulin.
	HIV virus identified as cause of AIDS
1984	Cal Bio scientists described in *Nature* the isolation of a gene for anaritide acetate, which helps to regulate blood pressure and control salt and water excretion.
	The Plant Gene Expression Center was established.
	Stanford University received a product patent for prokaryote DNA.
	Chiron Corp. announced the first cloning and sequencing of the entire human immunodeficiency virus (HIV) genome.
	Charles Cantor and David Schwartz developed pulsed-field gel electrophoresis.
	British geneticist Alec Jeffreys introduced technique for DNA fingerprinting to identify individuals.
	Oil at $40/barrel.
	Process for industrial drying of fuel alcohol using a corn based adsorbent in place of azeotropic distillation demonstrated on an industrial scale.
	Transgenic pig, rabbit, and sheep by micro injection of foreign DNA into egg nuclei.
	PRC developed at Cetus.
1985	Genetic fingerprinting entered the courtroom.
	Axel Ullrich reported the sequencing of the human insulin receptor in *Nature*. Bill Rutter's UCSF team described the sequencing in *Cell* two months later.
	Cal Bio cloned the gene that encodes human lung surfactant protein, a major step toward reducing a premature birth complication.
	Cetus Corporation's developed GeneAmp polymerase chain reaction (PCR) technology, which could generate billions of copies of a targeted gene sequence in only hours.
	Genetically engineered plants resistant to insects, viruses, and bacteria were field tested for the first time.
	The NIH approved guidelines for performing experiments in gene therapy on humans.
	Genetic Sciences surreptitiously performed the first deliberate release experiment, injecting genetically engineered microbes into trees growing on the company's roof, while waiting for approval from the EPA to conduct a different deliberate release experiment involving strawberry plants.
1986	UC Berkeley chemist Peter Schultz described how to combine antibodies and enzymes (creating "abzymes") to create pharmaceuticals.
	Orthoclone OKT3® (Muromonab-CD3) approved for reversal of acute kidney transplant rejection.
	A regiment of scientists and technicians at Caltech and Applied Biosystems, Inc., invented the automated DNA fluorescence sequencer.
	The FDA granted a license for the first recombinant vaccine (for hepatitis) to Chiron Corp.
	The EPA approved the release of the first genetically engineered crop, gene-altered tobacco plants.
	Phase down of lead as octane booster in gasoline in U.S. Created demand for nonleaded octane booster for liquid fuels.
	Ethanol production at 500×10^6 gallon/year for use as octane booster.
	Merck licensed Chiron's recombinant hepatitis B vaccine.
1987	Genentech received FDA approval to market rt-PA (genetically engineered tissue plasminogen activator) to treat heart attacks.
	Calgene, Inc. received a patent for the tomato polygalacturonase DNA sequence, used to produce an antisense RNA sequence that can extend the shelf-life of fruit.
	Advanced Genetic Sciences, Inc. conducted a field trial of a recombinant organism, a frost inhibitor, on a Contra Costa County strawberry patch.
	Maynard Olson and colleagues at Washington University invented "yeast artificial chromosomes," or YACs, expression vectors for large proteins.
	Recombivax-HB® (recombinant hepatitis B vaccine) approved.
	Interleukin (IL-2) by Cetus undergoes clinical trials.
	Aspartame sales at $500 million.
	Oil at $15 to $20/barrel.
1988	Harvard molecular geneticists Philip Leder and Timothy Stewart awarded the first patent for a genetically altered animal, a mouse that is highly susceptible to breast cancer.
	SyStemix Inc. received a patent for the SCIDHU Mouse, an immune-deficient mouse with a reconstituted human immune system. The mouse was engineered for AIDS research.
	Genencor International, Inc. received a patent for a process to make bleach-resistant protease enzymes to use in detergents.
	Hoffmann-La Roche, Inc. and Cetus Corp. negotiated a licensing agreement for two anti-cancer drugs, Interleukin-2 and Polyethylene Glycol Modified IL-2. This agreement became the prototype for cross-licensing between companies with parallel patents.

TABLE 1. (*Continued*)

Date	Event
	Tissue plasminogen activator (TPA) introduced by Genetech.
	Human genome project started
	Ethanol production at 800×10^6 gallons/year.
	Cetus requested approval for IL-2 to treat advanced kidney cancer
1989	UC Davis scientists developed a recombinant vaccine against the deadly rinderpest virus, which had wiped out millions of cattle in developing countries.
	Creation of the National Center for Human Genome Research, headed by James Watson, which will oversee the $3 billion U.S. effort to map and sequence all human DNA by 2005.
	Epogen® (Epoetin alfa) a genetically engineered protein introduced, providing a means to help patients with kidney failure.
	American Home Products purchased A.H. Robbins.
	Amgen introduced EPO (produced in 2-L roller bottles).
	Merrill Dow combined with Marion Laboratories for $7.7 billion.
	Bristol Myers and Squibb merged ($12 billion).
1990	UCSF and Stanford University were issued their 100th recombinant DNA patent license. By the end of fiscal 1991, both campuses had earned $\$40 \times 10^6$ from the patent.
	Actimmune® (Interferon gamma-1b) approved for treatment of chronic granulomatous disease.
	Adagen® (adenosine deaminase) approved for treatment of severe combined immunodeficiency disease.
	The first successful field trial of genetically engineered cotton plants, was conducted by Calgene Inc. The plants had been engineered to withstand use of the herbicide Bromoxynil.
	The FDA licensed Chiron's hepatitis C antibody test to help ensure the purity of blood bank products.
	Michael Fromm, molecular biologist at the Plant Gene Expression Center, reported the stable transformation of corn using a high-speed gene gun.
	Mary Claire King, epidemiologist at UC-Berkeley, reported the discovery of the gene linked to breast cancer in families with a high degree of incidence before age 45.
	GenPharm International, Inc. created the first transgenic dairy cow. The cow was used to produce human milk proteins for infant formula.
	The first gene therapy took place, on a four-year-old girl with an immune-system disorder called ADA deficiency. The therapy appeared to work, but set off a fury of discussion of ethics both in academia and in the media.
	The Human Genome Project, the international effort to map all of the genes in the human body, was launched. Estimated cost: $\$13 \times 19^9$. 1990 Formal launch of the international Human Genome Project.
	FDA rejected IL-2 application of Cetus.
	Hoffmann-LaRoche acquired 60% of Genetech for $\$2.1 \times 10^6$.
	Genetech's TPA earned $\$210 \times 10^6$.
	Protropin® (human growth hormone) earned $\$157 \times 10^6$.
	First attempt at human gene therapy.
	Amgen's EPO sales at $\$300 \times 10^6$/yr, in U.S. Licensed by Kilag (Johnson and Johnson in Europe) and Kirin (Japan).
	HFCS world sales estimated at about $\$3 \times 10^9$ (17×10^9 lb).
1991	The celebrated reference work "Mendelian Inheritance in Man," was made available through an on-line computer network. The catalogue lists some 5,600 genes known or thought on good evidence to be inherited in Mendelian patterns. *http://www3.ncbi.nlm.nih.gov/Omim/*
	Analyzing chromosomes from women in cancer-prone families, Mary-Claire King, of the University of California, Berkeley, found evidence that a gene on chromosome 17 causes the inherited form of breast cancer, and also increases the risk of ovarian cancer.
	Amgen EPO sales exceeded $\$293 \times 10^6$ by August 1991.
	Genetics Institute lawsuit against Amgen for American rights to EPO.
	American Home Products bought $\$666 \times 10^6$ (60%) share in Genetics Institute.
	Chiron purchased Cetus for $\$650 \times 10^6$.
1992	The U.S. Army began collecting blood and tissue samples from all new recruits as part of a "genetic dog tag" program aimed at better identification of soldiers killed in combat.
	American and British scientists unveiled a technique for testing embryos in vitro for genetic abnormalities such as cystic fibrosis and hemophilia.
	IL-2 (now owned by Chiron) approved for further testing by FDA.
	TPA (from Genentech) under competitive pressure from less expensive product by Swedish Kabi.
	Policy guidelines for the agricultural biotechnology established.
1993	Kary Mullis won the Nobel Prize in Chemistry for inventing the technology of polymerase chain reaction (PCR).
	Chiron's Betaseron (a β-interferon) was approved as the first treatment for multiple sclerosis in 20 years. Drug marketed by Berlex (owned by Schering AG).
	The FDA declared that genetically engineered foods are "not inherently dangerous" and do not require special regulation.
	The Biotechnology Industry Organization was created by merging two smaller trade associations.
	George Washington University researchers cloned human embryos and nurtured them in a Petri dish for several days. The project provoked protests from ethicists, politicians, and critics of genetic engineering.
	An international research team, led by Daniel Cohen, of the Center for the Study of Human Polymorphisms in Paris, produced a rough map of all 23 pairs of human chromosomes.
	Genentech launched Access Excellence, a $\$10 \times 10^6$ nationwide communications network program designed to enable high school biology teachers across the country to access their peers as well as experts.
	Health care reform proposals created uncertainty in biotechnology industry.
	Merck acquired Medco containment services for $\$6.6 \times 10^9$.
1994	The first genetically engineered food product, the Flavr Savr tomato, gained FDA approval.
	The BRCA1 gene, previously implicated in the development of rare familial forms of breast cancer, also found to appear to play a role in much more common types of noninherited breast cancers.
	A multitude of genes, human and otherwise, were identified and their functions described. These included: • Ob, a gene predisposing to obesity. • BCR, a breast cancer susceptibility gene. • BCL-2, a gene associated with apoptosis (programmed cell death) hedgehog genes (so named because of their shape, these produce proteins which guide cell differentiation in advanced organisms). • Vpr, a gene governing reproduction of the HIV virus.
	Linkage studies identified genes for a variety of ailments including: bipolar disorder, cerulean cataracts, melanoma, hearing loss, dyslexia, thyroid cancer, sudden infant death syndrome, prostate cancer, and dwarfism.
	Genetic researchers successfully transferred the CFTR (cystic fibrosis transmembrane conductance regulator) gene into the intestines of mice. This appeared to be a major step towards gene therapy for patients with cystic fibrosis. Researchers reported early success with a liposomal method for delivering the CFTR gene in humans.
	The approval of genetically engineered version of human DNAase, which breaks down protein accumulation in the lungs of CF patients. It was the first new therapeutic drug for the management of cystic fibrosis in over 30 years.
	Another group of researchers reported the first successful systemic selective inhibition of gene expression using antisense oligonucleotides.
	Centocor's ReoPro cleared for marketing in United States by the FDA and by the European Union's regulatory body, CPMP for patients undergoing high-risk balloon angioplasty.
	Genzyme's Ceredase®/Cerezyme® (alglucerase/recombinant alglucerase) approved for type 1 Gaucher's disease.

(*continued*)

TABLE 1. (*Continued*)

Date	Event
	The first crude but thorough linkage map of the human genome appeared (see *Science*, **265**, (Sept.30, '1994), for the full color pull-out).
	The year also saw an increase in squabbling over who owns what parts of the genome. The scientists and research corporations have worked out a way to share access to a computerized database detailing 35,000 human genes.
	Researchers at the University of Texas reported that the enzyme telomerase appears to be responsible for the unchecked growth of cells seen in human cancers. The discovery could lead to many new diagnostic and therapeutic applications.
	Recombinant GM-CSFapproved for chemotherapy-induced neutropenia.
	American Home Products bought American Cyanimid.
	Roche Holding, parent of Swiss Drug company Hoffmann-LaRoche bought Syntes for $5.3 billion.
	SmithKline Beecham merged with Diversified Pharmaceutical Services ($2.3 billion) and Sterling Winthrop ($2.9 $\times$ 10^9).
	Eli Lilly acquired PCS Health Systems for $4.1 $\times$ 10^9.
	Bayer purchased Sterling Winthrop NA for $1.0 $\times$ 10^9.
	Based on corn adsorbent dries half of fermentation ethanol in U.S. (750 $\times$ 10^6 gallons/yr).
1995	A European research team identified a genetic defect which appears to underlie the most common cause of deafness Kok et al. *Science*, **267**, (Feb. 3, 1995).
	Researchers at Duke University Medical Center transplanted hearts from genetically altered pigs into baboons, proving that cross-species operations are possible. Later, the first baboon-to-human bone marrow transplant was performed on an AIDS patient.
	The first full gene sequence of a living organism other than a virus was completed for the bacterium Hemophilus influenzae. See: Smith et al., *Science* **269**, 495–511 (July 28, 1995): and associated commentary, pp.468–470.
	Former football player O.J. Simpson was found not guilty in a high-profile double-murder trial in which PCR and DNA fingerprinting played a prominent, but apparently unpersuasive role.
	Investigators at the Centers for Disease Control and Prevention confirmed that the Ebola virus is behind outbreak of hemorrhagic fever in Zaire.
	Hitherto unrecognized properties of RNA added further support to the idea that RNA was the central molecule in the origin of life.
	Leptin, a protein product of the recently identified obesity gene (ob) appeared to cause weight loss in experimental animals. *Journal Nature Medicine* (1995).
	A new gene mapping technique, STS gene mapping, thought to greatly speed the work of geneticists involved in the international Human Genome Project. *Nature Genetics.* (1995).
	A single gene identified that appears to control the growth and development of eyes throughout the animal kingdom. Halder et al., *Science*, **267**, 1788–1792, (1995).
	A new transgenic mouse carrying a gene for human Alzheimer's disease developed. Games et al. *Nature*, **373**, 476–477, 523–537 (1995).
	Gene therapy, immune system modulation and genetically engineered antibodies entered the clinic in the war against cancer. The *Journal of Clinical Oncology*. (1995).
	UpJohn and Pharmacia merged to form Pharmacia-UpJohn in a $6 $\times$ 10^9 stock swap.
	Hoescht/Marion Merrell Dow merged for $7.1 $\times$ 10^9.
	Glaxo/Wellcome merged in a $15 $\times$ 10^9 deal.
1996	Biogen's recombinant interferon drug. Avonex® approved for the treatment of multiple sclerosis.
	A collaboration of scientists reported sequencing of the complete genome of a complex organism, *Saccharomyces cerevisiae*, otherwise, known as baker's yeast. The achievement marked the complete sequencing of the largest genome to date: more than 12 million base pairs of DNA. I
	Analysis of a small meteorite that landed on Antarctica some 15 $\times$ 10^6 years ago sparked what may be the greatest scientific discovery ever, possible evidence of life on Mars.
	The sequencing of the genome of ancient organisms, archaea, found in inhospitable climates deep in thermal vents under the sea thought to greatly advance understanding of the evolution of life on Earth. The microorganisms are neither eukaryotes nor prokaryotes. *Science*; (1996).
	A new inexpensive diagnostic biosensor test for the first time allowed instantaneous detection of the toxic strain of *E. coli* (*E. coli* strain 0157:H7), the bacteria responsible for several recent food-poisoning outbreaks.
	The discovery of a gene associated with Parkinson's disease provided an important new avenue of research into the cause and potential treatment of the debilitating neurological ailment. *Science*; (1996).
	Monsanto purchased Ecogen for $25 $\times$ 10^6, Dekalb Genetics for $160 $\times$ 10^6. Agracetus for $150 $\times$ 10^6; and 49.9% of Calgene.
	American Home Products purchased the remaining 40% stake in Genetics Institute, Inc. for $1.25 $\times$ 10^9.
	Biogen introduced Avonex, to compete with Berlex's Betaseron for MS sufferers.
	$27 $\times$ 10^9 merger of Ciba-Geigy AG and Sandoz AG to form Norvatis approved. Estimated annual sales of $27.3 $\times$ 10^9. U.S. Federal Trade Commission (FTC) prevented monopoly that does not yet exist by requiring Norvatis to provide access to key genetic-research discoveries. The goal of the FTC: to prevent company from dominating gene-therapy research.
	Hoechst Schering AgrEvo purchased PGS International for $730 $\times$ 10^6, thereby obtaining access to technology for constructing transgenic plants resistant to an AgrEvo broad spectrum herbicide, and for introducing Bt toxin gene.
1997	Monsanto completed purchase of Calgene for $320 $\times$ 10^6. Agreed to buy Asgrow Agronomics Soybean business for $240 $\times$ 10^6, and Holden's Foundation Seeds (corn, sales of $50 $\times$ 10^6/yr) for $1.02 billion.
	Proctor and Gamble paid Regeneron $135 $\times$ 10^6 to carry out research on small-molecule drugs.
	SmithKline Beecham formed joint venture with Incyte to enter genetic-diagnostics business.
	Schering-Plough Corporation acquired Mallinckrodt Animal-Health Unit for $405 $\times$ 10^6.
	Merck, Rhône-Poulenc formed animal health care 50-50 joint venture (Merial Animal Health). Estimated annual sales were $1.7 billion).
	Novartis purchased Merck and Co.'s insecticide and fungicide business (sales of $200 $\times$ 10^6/yr) for $910 $\times$ 10^6.
	Roche Holding, parent of Swiss Drug Company Hoffmann-LaRoche bought Boehringer Mannheim for about $11 $\times$ 10^9.
	Proctor and Gamble signed $25 $\times$ 10^6 agreement with Gene Logic to identify genes associated with onset and progression of heart failure.
	Dupont purchased Protein Technologies (division of Ralston Purina) for $1.5 $\times$ 10^9 as part of business plan to develop soy protein foods.
	American Home Products discussed $60 $\times$ 10^9 merger with SmithKline Beecham PLC.
	Monsanto spun off chemicals unit and becomes Monsanto Life Sciences.
	Researchers at Scotland's Roslin Institute reported that they had cloned a sheep-named Dolly-from the cell of an adult ewe. Polly, the first sheep cloned by nuclear transfer technology bearing a human gene, appeared later. See also **Cloning (The Story of Dolly the Sheep)**.
	Artificial human chromosomes created for the first time. *Nature Genetics.* (1997).
	Follistim, a recombinant follicle-stimulating hormone, approved for treatment of infertility.
	Scientists at the Oregon Regional Primate Research Center, cloned two Rhesus monkeys from the early stage embryos using the nuclear transfer method.

TABLE 1. (*Continued*)

Date	Event
	Leading geneticists expressed shock and dismay as word spread of the U.S. Patent and Trademark Office announcement that it would allow patents on expressed sequence tags (ESTs), short sequences of human DNA that have proven useful in genome mapping.
	Orasure, a bloodless HIV-antibody test using cells from the patient's gums approved, *JAMA*, (1997).
	Researchers at Northwestern University used a kind of reverse-knockout approach to identify the Clock gene. The first gene providing the circadian rhythm of mammalian life has now been identified.
	Using a bit of DNA and some commonplace biological laboratory techniques, researchers engineered the first DNA computer "hardware" ever: logic made of DNA. The research was announced at the First International Conference on Computational Molecular Biology in Santa Fe, NM.
	A new *E. coli* vaccine for prevention of urinary tract infections developed.
	The complete genome of the Lyme disease pathogen, *Borrelia burgdorferi*, sequenced, along with the genomes for *E. coli* and *H pylori*. *Nature*; (1997).
	A new DNA technique combined PCR, DNA chips, and computer programming providing a new tool in the search for disease-causing genes without the necessity of costly DNA sequencing.
	The FDA approved Rituxan, the first antibody-based therapy for cancer (for patients with non-Hodgkin's lymphoma).
1998	University of Hawaii scientists cloned three generations of mice from nuclei of adult ovarian cumulus cells. *Nature*; (July 23, 1998).
	The FDA granted marketing clearance to RemicadeTM (infliximab), a novel monoclonal antibody for treatment of Crohn's disease.
	Research teams from The University of Wisconsin and Johns Hopkins University succeeded in growing embryonic stem cells, the long sought grail of molecular biology. *Science*; (Nov 5, 1998) and *Proceedings of the National Academy of Sciences*, (Nov 1998.)
	Scientists at Japan's Kinki University cloned eight identical calves using cells taken from a single adult cow.
	Favorable results with a new antibody therapy against breast cancer, HER2neu (Herceptin), heralded a new era of treatment based on molecular targeting of tumor cells
	Fomivirsen became the first approved therapeutic agent developed with antisense medical technology.
	The first complete animal genome the *C. elegans* worm was sequenced. *Science;* (Dec 11, 1998).
	A rough draft of the human genome map was produced, showing the locations of more than 30,000 genes, *Science* **282**, 744–746; (1998).
	Smith Kline Beecham broke off talks with American Home Products.
	Glaxo entered merger discussions with SmithKline Beecham in a deal valued at \$65–70 10^9. Merger discussions driven by the successful hunt for human genes and opportunities for exploiting these findings for development of new pharmaceuticals.
1999	A new medical diagnostic test for the first time allowed quick identification of BSE/CJD a rare but devastating form of neurologic disease transmitted from cattle to humans,
	A new technique based on unique individual antibody profiles offered an alternative to current DNA fingerprinting methods. The method is simple to use and has attracted considerable attention from law enforcement.
	Genentech to remain independent company, Roche intended to exercise its call option and publicly reissue Genentech shares.
	Genentech issued new t-PA patent and files patent infringement suit against Centocor's thrombolytic agent.
	FDA approved Nutropin Depot™, first long-acting dosage form of recombinant growth hormone for growth hormone deficiency in children.
	FDA approves efficacy results for spine bone mineral density in childhood-onset growth hormone-deficient adults.
	COR Therapeutics, Schering-Plough and Genentech announce plans to study INTEGRILIN eptifibatide, injection in combination with TNKase–tenecteplase, in heart attack patients.
	Genentech and Immunex announce patent license agreement for immuno-adhesin technology for ENBREL.
	Immunex Corporation and Genentech, Inc. join forces to develop TRAIL/Apo2L in cancer.
2000	Actelion and Genentech sign licensing agreement for Tezosentan in the U.S.
	Genentech announces clinical trials testing TNKase™ (Tenecteplase) with leading antithrombotics for treatment of heart attack.
	Genentech and Novartis submit application for FDA approval of anti-IgE antibody.
	DNA sequencing of Human Genome roughly completed.
2001	OSI Pharmaceuticals, Genentech and Roche to develop and commercialize OSI-774, OSI's lead cancer drug.
	COR, Schering-Plough, and Genentech announce U.S. collaboration INTEGRILIN® (eptifibatide) injection, TNKase™ (Tenecteplase) and Activase® (Alteplase, recombinant).

[a] *Note*: "the field of biotechnology" continues to evolve and grow at a breath-taking rate, therefore some of the entries in this table will have resulted in different outcomes than initially thought.

enhance their function and to produce useful products in new ways." Since the alteration of the cells is carried out by inserting new genes into the DNA of the organisms in a rational, rather than random, manner, the process has popularly been referred to as "genetic engineering." This report, and another one that had preceded it, had recognized that the new biotechnology was setting the stage for unprecedented growth in products, markets, and expectations, and that there was a need for substantial manufacturing capability to bring about the application of biotechnology for the benefit of society.

The U.S. industry based on the new biotechnology is projected to grow to \$50 billion by the 21st century. This industry has the potential to surpass the computer industry in size and importance because of the pervasive role of biologically produced substances in everyday life. The transition from basic discovery to production through scale-up of bioprocesses will be a key element in the growth of the industry that will impact products and production methods in the chemical, fermentation, and food processing industries. By 1998, the impact of the new biotechnology on the pharmaceutical industry was becoming profound. Its potential effect on food processing and production agriculture was resulting in multibillion dollar investments by some of the world's largest chemical companies (Fritsch and Kilman, Kilman, 1996, 1998). In 1997, Monsanto sold off its chemical business with sales of about $\$4 \times 10^9$ ($10^9 = 1$ billion) to form an entity known as Solutia, in order to focus on its more profitable agricultural, food ingredients, and pharmaceutical businesses with sales of over $\$5 \times 10^9$ (Fritsch). Dupont, Dow Chemical, Norvatis, and Monsanto were investing heavily or acquiring food technology, plant biotechnology, and seed companies at costs of billions of dollars by early 1998. Bioengineered foods is one target of these acquisitions. Fat-free pork, vegetarian meat, bread enriched with cancer fighting compounds and corn products that fight osteoporosis are part of these companies' vision and future profits of biotechnology (Kilman, 1998).

New biotechnology methods enable rapid identification of genes and their protein products, and facilitate new drug candidates from combinatorial chemistry. The discovery of biochemical nature of diseases, and identification of ways by which drugs can interfere with the disease process has been greatly accelerated by the new biotechnology and by the identification of genes that represent underlying mechanisms of disease. The new genes are patentable, hence giving a twenty year monopoly to the companies first to identify and patent them (Kinoshita). This capability also speeds up drug discovery. The resulting candidates hold the promise of new and more potent medicines.

Although genomics (i.e., gene-identifying technology) provides information on the targets or sites upon which drugs can act, combinatorial chemistry and the automation of chemical synthesis make it possible to generate thousands of candidates rapidly. There conducted could be tested against targets identified through genomic methods. This in turn is driving the merger of drug companies to make resources and multibillion dollar

research budgets available to screen, develop, and test the new drugs resulting from the combination of computerized gene-discovery and automated synthesis of molecules with potential as drugs. The largest merger proposed to date (in early 1998) was that of Smith Kline Beecham PLC and Glaxo Wellcome PLC, in a deal valued at between \$65 and 70×10^9. Annual sales of the combined companies would be on the order of $\$25 \times 10^9$ (Tanouye and Langreth).

Products from the new plant biotechnology are changing the structure of large companies that sell agricultural chemicals. The chemical, food and agricultural industries also began to experience major changes by the mid 1990s, catalyzed by advances in plant biotechnology and by the ability to identify and manipulate traits of economically important crops at the cellular level. The first commercial success of plant biotechnology came in 1996, after about 20 years of research and development in the genetic engineering of crops. In this case, Monsanto had shown that soybean seeds, genetically engineered to resist the herbicide, Round-up, gave higher yields. The herbicide could be applied to kill all other plants in a field while having no effect on the soybean plants. The introduction of genetically engineered seeds fostered concerns about transgenic supercrops. Could these breed super weeds if genes from widely planted and cultivated, weed resistant plants were to migrate to wild relatives (Kling). The risk is perceived to be small. However, France, a major corn producer, prohibited planting (but not consumption) of transgenic corn (Balter).

Another genetically altered product by Monsanto, introduced in 1996, was cotton seed that contained a gene from bacterium, *Bacillus thuringiensis*. The gene enables the bacterium, and now the cotton plants, to make a protein that is toxic to bollworms and tobacco budworms, thereby reducing the need for pesticides that are otherwise needed to control insect infestations (Fritsch and Kilman). The *Bacillus thuringiensis* gene has also been incorporated into potato so that it produces a protein toxic to the Colorado potato beetle. The potato has been approved for use in Canada (Yanchinski). Dow-Elanco through its investment in Mycogen (a San Diego based biotechnology company) has marketed transgenic corn with *Bacillus thuringiensis*-based resistance to the European Corn Borer (Thayer, 1996).

There were 30 crop species that, by 1996, had been engineered to express *Bacillus thuringiensis* endotoxins. These proteins are highly toxic to specific insect pests. There are concerns of the evolution of insects that are resistant to these toxins since millions of acres are now being planted with these crops. (Ives). If insect species develop that are resistant to *Bacillus thuringiensis* endotoxin, strategies for overcoming this resistance will need to be developed, resulting in a cycle of further manipulation of the plants genes to alter the toxins (Ives). Nonetheless, the use of this class of bioproduct is rapidly growing. Success of the transgenic soybean seeds, insect resistant cotton seeds, and other genetically engineered seeds have resulted in predictions, from market analysis, that sales would grow to $\$6.5 \times 10^9$, annually, within 10 years (Fritsch and Kilman).

The current growth of the agricultural biotechnology sector may, in part, have benefited from a 1992 ruling in which policy guidelines were defined on how the Food and Drug Administration would oversee new plant varieties, included those developed through biotechnology. Their basis was "that products would be judged by their risks ... not by the process which produces them." Hence if the composition of a food product is not significantly altered, the FDA's premarket approval would not be needed, and special labeling would not be required. However, if "genetic manipulation were to lead to a product that has increased allergenicity, or that contains new proteins, fats, or carbohydrates, it will have to pass rigorous premarket review. And if approved its new traits will have to be labeled," according to Ember. At the time of this announcement in 1992, overall sales of biotechnology were estimated to be $\$4 \times 10^9$ annually, and expected to grow to $\$50 \times 10^9$ by the end of the 20th century. Of these revenues, the agricultural market was projected to be about $\$28 \times 10^9$ (Ember). The widespread tests and apparent initial success of several genetically engineered crops, about four to six years later, may have benefitted from this policy, proposed under the Bush administration. The timeline between 1992 and 1997 shows that a combination of, technical, business, and regulatory factors coincided at about the same time, and culminated in the first significant commercialization of plant biotechnology products by 1997 (see timeline in Table 1).

Hileman summarized the status of regulation, concisely in 1995, as follows. The statutes divide agricultural products into six categories: plants engineered for (1) herbicide resistance, (2) pesticide resistance, (3) delayed (tomato) ripening; (4) plants modified to make products otherwise obtained from other crops; (5) plants engineered so their crop can be processed more easily; and (6) bacteria enhanced to fix nitrogen or control insects. Genetically modified plants and animals for purposes of producing pharmaceuticals are not included in these categories. Although few products from transgenic plants require agency approval, most companies have voluntarily consulted the FDA to obtain its stamp of approval. Transgenic plants to be grown on a large scale are regulated by the U.S. Department of Agriculture (USDA). The U.S. Environmental Protection Agency (U.S. EPA), regulates gene-modified organisms that express a pesticide or function as a pesticide. Genetically engineered microorganisms, such as a bacterium engineered to produce ethanol, would also be regulated by the U.S. EPA. *Bacillus thuringiensis* corn is regulated by all three agencies: insecticidal properties by the EPA; large-scale growing by the USDA; and corn as a food product by the FDA.

Growth of the Fermentation Industries

The history of bioprocessing probably started with bread making, which utilized yeast, about 6000 years ago. Fermentation of grains and fruits to alcoholic beverages was carried out in Egypt, and other parts of the ancient world about 2500 B.C. Other types of food fermentation practiced for thousands of years included the transformation of milk into cheeses, and fermentation of soybeans to give sauces and cheeses. However, it was not until 1857, that Pasteur proved that alcoholic fermentation was caused by living cells, i.e., yeasts. The intentional manipulation of microbial fermentations to obtain food products, solvents, and beverages, and later, substances having therapeutic value as antimicrobial agents for fighting infections (Aiba et al., Evans), continued to give rise to a large fermentation industry over the next 100 years.

Submerged Fermentations. Submerged fermentations represent a technology in which microorganisms are grown in large agitated tanks filled with liquid fermentation media consisting of sugar, vitamins, and minerals. Many of the fermentations are aerated, with vigorous bubbling of air providing the oxygen needed for microbial growth. Since the microorganisms are in a liquid slurry, they are considered to be submerged, compared to microbial growth that occurs on a surface (such as on a moldy fruit or piece of bread).

The fermentation industry produced food and beverage products, and some types of oxygenated chemicals by submerged fermentations prior to the first submerged antibiotic fermentations in 1943. Products in the early 20th century included ethanol, glycerol, acetone, and butanol. However the growth of an efficient petrochemical industry, in the years following the Second World War, made some of these fermentation products economically unattractive. Petroleum sources supplanted many of the large volume fermentation products, with the exception of ethanol produced with government subsidies, yeasts for baking, vinegar, carboxylic acids, and amino acids for use as food additives and in the formulation of animal feeds. These large volume fermentations depended on the availability of molasses or glucose from corn (starch) as the fermentation substrates as well as the ability to grow organisms in large tanks (Hacking).

Oil Prices and the Fermentation Industry. The low prices of oil prior to 1973 made the manufacture of many oxygenated chemicals by fermentation uneconomical. The low oil prices stimulated research and development on single cell protein and attempts to commercialize it. Large, aerated fermentations utilized methane or methanol (from petrochemical processing) as the main substrate in order to grow the cells. The goal was to propagate microorganisms, whose protein content would make them attractive as a food source, using a relatively inexpensive substrate derived from petroleum. Since these fermentations were based on the growth of unicellular microorganisms, the source of the protein was appropriately named single-cell protein. However, concerns about carry-over of harmful substances from the petroleum source into the fermentation, where it would be incorporated into the edible cellular biomass, coupled with a sharp rise in oil prices in 1973, and subsequent decreases in soybean prices (a vegetable source of protein), made single-cell protein processes unattractive.

At the same time that the prices of crude oil quadrupled in late 1973 and 1974, in part triggered by a war in the Middle East, the combined use of restriction enzymes (that cut DNA in a directed manner) and ligases (i.e., enzymes that join foreign genes with the DNA of the host cell) was demonstrated. Stanley Cohen and Herbert Boyer showed that DNA could be cut and rejoined in new arrangements in a directed manner. Their work

gave birth to the field and the industry based on new forms of organisms obtained through the sequencing, removal, insertion, and amplification of genes across different species of organisms. While the old, high volume fermentation industry based on inexpensive petroleum was lost, a new high-value, lower volume fermentation industry was evolving (Hacking, Olsen).

Value-added Products. The economic impact of value-added chemicals derived through fermentations is currently modest, but the potential is clear. For example, in 1997, Dupont and Genencor developed an inexpensive and environmentally friendly fermentation for making polyester building blocks from glucose. This process is based on a proprietary, recombinant microorganism which combines bacterial and yeast pathways so that the fermentable sugar is converted to glycerol, and the glycerol to trimethylene glycol, which in turn is polymerized to polyester. The resulting polymer is reported to have properties, which are superior to existing polyesters derived from petrochemical building blocks (balter).

Another example is a genetically engineered bacteria that can convert naphthalene (historically, priced much lower than indigo, as low as $1.00/kg) to indigo (priced at $8–17/kg). Indigo is used to dye blue jeans, has an annual market of $\$250 \times 10^6$, and accounts for 3% of all of the dye colors currently used. This dye, given the name, "bio-indigo," was proposed to replace dye currently made using cyanide and formaldehyde (O'Hamilton). The market for this biotechnology product is not yet clear although the potential benefits of this material could cause it to evolve into an economic success (O'Hamilton). The enzyme that enables this conversion and the genetically engineered bacteria that gave the result were discovered at Amgen. The technology was sold to Genencor International Inc., in 1989, when one of Amgen's biopharmaceuticals began to take-off and caused Amgen to drop its research on industrial enzymes (see timeline Table 1).

Growth of the Antibiotic/Pharmaceutical Industry

The genesis of the antibiotic industry, which preceded the current era of engineered organisms, was catalyzed by government incentives and support during World War II. The motivation was both the discovery of the beneficial effects of penicillin and the difficulty of producing penicillin through chemical synthesis. Once the fermentation route was chosen over chemical synthesis, events progressed rapidly. At first, production was tried by growing the *Penicillum* on the surface of moist bran. This did not work well because it was difficult to control temperature and sterility. The second approach was to grow the microorganism on the surface of quiescent liquid growth medium in milk bottles and other types of containers. Yields were high, but potential for mass production was limited. This led to fermentations in large, agitated vessels that held a liquid volume of 7000 gallons or more (Shuler and Kargi).

The rapid scale-up of production required development of a cost-effective medium on which the penicillin producing microorganism, *Penicillin chrysogenum*, was grown, design of large-scale-aerated tanks that could be operated under sterile conditions, and recovery and purification of the final product. The first submerged fermentations were carried out on corn steep liquor–lactose based medium. Recovery of the labile penicillin molecule was achieved through a combination of pH shifts and rapid liquid–liquid extraction (Shuler and Kargi). According to Hacking, "the discovery of penicillin, which has now virtually passed into folklore, has been one of the major milestones of the twentieth century, and arguably one of the most beneficial discoveries of all time. Its impact on biotechnology, and the public perception of biotechnology should not be underestimated." Hacking also points out that the development of cost-effective processes for manufacture of penicillin provides an example of the impact of government support in starting up a new technology with the potential of widespread benefits for society. "During the Second World War, the U.S. government imposed an excess profits tax of 85% as one measure to pay for the war effort. As many pharmaceutical companies were liable for this tax, additional research cost them effectively only 15% of its total cost, "the 15 dollar." Several of the early large antibiotic screens and process development of penicillin were funded on this basis (Hacking)." This led to the growth of a fermentation based antibiotic industry (see 1943 in timeline Table 1).

Penicillin. In 1877, Pasteur and Joubert discovered that anthrax bacilli were killed by other bacteria. In 1896, Gosio isolated mycophenolic acid from *Penicillum brevi-compactum*. Mycophenolic acid inhibited *Bacillus anthracis*, but was too toxic to be used as a therapeutic agent. By 1917 Grieg-Smith showed actinomycetes give substances with antibacterial activity. In 1928, Alexander Fleming showed staphylococcus cultures were inhibited by growing colonies of Penicillum notatum. (Unlike many of the other antibiotics at that time, penicillin was later found to be effective as well as suitable for systemic use). By 1937, actinomycetin, an antibacterial agent, had been isolated from a streptomycete culture, but was again too toxic for use as a therapeutic agent. In 1939, Dubos obtained gramacidin and tyrocidin from the spore-bearing soil bacillus, Bacillus brevis. These agents proved to be effective for treatment of skin infections (topical use) but again were too toxic for internal systemic use.

Penicillin was the first antibiotic suitable for human systemic use. Experience with penicillin during World War II showed it to be one of the few antibiotics, available at that time, which was suitable for systemic use to fight infections and save thousands of lives (Evans). Florey and Chain catalyzed the rediscovery of Fleming's penicillin, starting in 1939, during studies of compounds that would lyse bacteria. Their work was carried out in search of new therapeutic agents for use in the World War. Fleming's strain of *P. notatum* did not produce large amounts of penicillin, and penicillin itself was relatively unstable. Thus, significant efforts were carried out to develop isolation and purification procedures that minimized product loss. In a pattern, which continues to be repeated to this day, the researchers developed methods for isolating small quantities of penicillin for trials with mice. The penicillin was shown to protect the mice against *Streptomyces haemolyticus* while being relatively nontoxic. Clinical trials in 1941 were most successful, and scale-up to obtain larger amounts of the antibiotic were then initiated by joint Anglo-American efforts that included the involvement of Merck, Pfizer, and Squibb with the help of government laboratories (Aiba et al.).

Discovery, selection, and development of microorganisms suitable for submerged fermentations made penicillin's mass production possible. Penicillin was at first produced by surface culture, with the mold being grown on the surface of a nutrient medium in 1–2 liter batches in vessels resembling milk bottles. Antibiotic yield was improved by discovery of higher yielding strains of *P. notatum* and *P. chrysogenum* and mutants obtained by ultraviolet and x-ray irradiation of several *Penicillum* strains.

Scale-up from 1 to 2 L to 100,000 L capacity was made possible by the discovery of a strain of *P. chrysogenum* (on a moldy cantaloupe in Peoria, Illinois) which could be grown in submerged culture, and by the development of submerged fermentation technology for this microbe in large agitated vessels by USDA's Northern Regional Laboratories in Peoria. Mass production was now possible, since the microorganism could be grown in large liquid volumes of nutrient media to which sterile air was provided to satisfy oxygen requirements for growth (Aiba et al. and Evans). Prices of penicillin quickly decreased because of productivity gains made possible by submerged fermentation.

Acler Actiluatics. Other antibiotics were quickly discovered after the introduction of penicillin. A different type of antibiotic, streptomycin, which is active against a wider range of pathogens than penicillin and is a potent inhibitor of *Mycobacterium tuberculosis*, was isolated from a strain of actinomycete from the throat of a chicken by Waksman at Rutgers in 1944 (Aiba and Evans). Actinomycetes are commonly found in soil and are intermediate between fungi and bacteria. Since 1944, numerous other metabolic products of actinomycetes have been isolated and have made a transition from the bench scale to wide therapeutic use.

Between 1945 and 1965, about 30 new antibiotics gained the status of established therapeutic agents. By 1981, about 5500 antibiotics were identified with only 100 on the market. The number grew to about 160 variations of 16 basic compounds by 1996, together with an alarming rise in antibiotic and antibacterial resistant bacterial infections (Stinson). This array of products was based on the discovery of thousands of new antibiotics, of which only a few hundred were characterized, during the same time period (Aiba et al., Hacking). This illustrates how successful development of therapeutic agents derived from microbial sources requires tremendous screening efforts. There is a continuing need for antibiotic discovery and development as drug-resistant infections have begun to appear, with drug-resistant bacteria now being viewed as a threat that is just as serious as the AIDS (HIV) epidemic (Stinson and Tanouye).

Stinson gives a clear description of the difference between antibiotics and antibacterial drugs. Antibiotics are drugs that kill bacteria and are derived from natural sources such as molds. Chemically synthesized antibacterial drugs, whose structures are the same as antibacterials from natural sources are also antibiotics. Hence, penicillin G from

Penicillum chrysogenum, or organically synthesized ceftriaxone with the same 7-aminocephasosporanic acid nucleus as compounds derived from *Cephalosporium* molds are antibiotics. "Antibiotics that are toxic to human cells, and to malignant human cells more so than normal ones," are anticancer antibiotics. Examples of antibacterial drugs are quinolones, oxazalidinones, and sulfa drugs. Some antibacterial drugs are also active against fungal, viral, or parasitic microorganisms. For example, *Helicobacter pylori* infections are now treated with antibacterial drugs. *H. pylori* infections of the stomach wall are found in 95% of patients with duodenal ulcers, and 80% of patients with stomach ulcers (excludes patients who take nonsteroidal, antiinflammatory drugs).

Discovery and Scale-up. This synopsis of penicillin and antibiotic development illustrates how discovery and scale-up are synergistic. Following discovery, enough of the new substance must be obtained for testing with animals, and later, if warranted, for treating humans. The ability to scale-up production of a promising therapeutic agent rapidly complements the discovery process by providing sufficient material so that it can be characterized in detail on what a new compound can do. This help to provide input on where future discovery efforts might be directed. The second role of scale-up is to be able to provide larger quantities of pure drugs for clinical trials. Last, but not least, if the trials are successful, scale-up is needed to provide manufacturing capability to make the new drug available on a wide basis.

Pharmaceutical Industry Growth. The pharmaceutical industry has invested heavily in research to invent, screen, develop, and test new products. The industry has historically invested between 16 and 20% of its earnings in research, and has been continually concerned about developing new products, and keeping its pipeline full of new pharmaceuticals. Although the production of pharmaceuticals is sometimes perceived to be principally a fermentation- and biotechnology-based industry, many drugs are obtained through chemical synthesis or chemical modification of fermentation-derived molecules. It is estimated that pharmaceuticals accounted for half of the $\$45 \times 10^9$ fine chemical sales, worldwide, in 1991. Custom drug discovery, synthesis and marketing is carried out on a time-scale similar to biopharmaceuticals, with 10 years often being required to develop a product from discovery to routine production, where routine production is classified as 500 kg/year or more (Stinson). The combination of fermentation derived and chemically synthesized drugs, show that there has been a significant increase in the overall sales of the top ten companies, as well as a major change in their relative ranking based on sales (see Table 2). While the U.S. sales of drugs by US pharmaceutical companies exceeded $\$32 \times 10^9$ in 1991, the U.S. sales of protein biopharmaceuticals, was only $\$1.2 \times 10^9$. By 1996 the sales value of the biopharmaceuticals had grown to $\$7.5 \times 10^9$ (Anonymous, 1992; Thayer, 1991).

Despite the large increase in sales, the cost of prescription drugs as a fraction of health care costs remained constant at 4 to 5% of health care expenditures during this period (Reisch, 1993). Health care costs, which as of 1998 were contained, had risen very rapidly in the period from 1982 to 1992 from about $\$300 \times 10^9$/year to $\$820 \times 10^9$/year, respectively. The rapid increase during this ten year period led to close examination of medical costs, including costs of prescription drugs. One report suggested that the industry priced their drugs 4.3% higher than needed to recover research and development costs. At about the same time, the Pharmaceutical Manufacturer's Association (PMA), which represents companies that account for 90% of US pharmaceutical sales, proposed to limit aggregate price increases to no greater than the general rate of inflation as measured by the government's consumer price index. The PMA did not wish to appear to act in restraint of trade and hence first sent the proposal to the antitrust division of the Department of Justice (Reisch, 1992).

The estimated 1997 sales in Table 2, in part, reflect the growth of revenues from areas other than nonprescription drugs. Despite constraints on prices, the need and markets for new pharmaceuticals is large, and will continue to grow as the population grows and ages. The fit of new biotechnology products into this growing market, and the pending loss of patent protection of existing drugs, help to explain the increasing pace of consolidation in the pharmaceutical industry since about 1995 (Thayer, 1995). The pending loss of patent protection will affect, or has affected, major products from Merck & Co., Schering-Plough, Eli Lilly, Glaxo, Bristol-Myers Squibb, Syntex (now a part of Roche), UpJohn (now Pharmacia-UpJohn) and Astra AB. An example of the effect of loss of patent protection is given by heart drug Capoten (Bristol-Myers Squibb), whose US sales fell from $\$146 \times 10^6$ to $\$25 \times 10^6$ within a year after coming off patent. The price of the medicine dropped from 57/pill to 3/pill when generic versions of the drug entered the market. Other examples of drugs that will come off patent between 2000 and 2002, given by Tanouye and Langreth, have total current U.S. sales of $\$6.8 \times 10^9$ among four U.S. companies. Hence, both economics and technology are likely to play a role of the expansion of the products and processes, based on the new biotechnology, into the pharmaceutical industry.

TABLE 2. SALES OF TOP 15 PHARMACEUTICAL COMPANIES IN 1991[a]

Companies	Approximate Pharmaceutical Sales (1991)[b]	Estimated 1997[c]
U.S. Pharmaceuticals		
Baxter International	NA	6.0
Merck and Co.	6.37	22.9
Bristol-Myers Squibb	5.26	16.2
Eli Lilly	3.70	7.9
American Home Products	3.46	14.2
Johnson and Johnson	3.30	22.9
Pfizer	3.23	11.8
Abbott Laboratories	3.16	11.8
Warner-Lambert	3.08	7.5
Schering-Plough	NA	6.6
Sub-Total	31.6	127.8
International		
Glaxo (UK)	6.05	
Hoeschst-Roussel (Germany)	4.99	
Bayer (Germany)	4.96	
Ciby-Geigy (Switzerland)	4.58	
SmithKline Beechem (UK/US)	4.24	
Sandoz (Switzerland)	4.09	
Hoffmann-LaRoche (Switzerland)	3.46	
Sub-Total	32.4	
TOTAL of 15.	64.0

[b] NA = not available.
[c] Estimated from first half sales and earnings reported by Thayer (1997), and multiplying by two.

Growth of the Amino Acid/Acidulant Fermentation Industry

The production of α-amino acids has a long history, starting with the isolation of asparagine from asparagus juice in 1806. The other α-amino acids were isolated from a variety of natural substances with threonine from fibrin being the last of these acids to be isolated and identified in 1935 (DeGussa, 1985). Glutamic acid, in the form of monosodium glutamate (MSG), was identified by Ikeda in 1908 as the agent responsible for the flavor enhancing properties of konbu, a traditional seasoning (food) additive in Japan. This discovery helped to initiate the development of an amino acid production industry starting in 1909, when amino acid hydrolysates of wheat gluten (protein) or soybean protein were used by Ajinomoto (Japan) to (Hirose et al.) commercially produce MSG. The discovery of the glutamic acid producing bacteria *Micrococcus glutamicus* (later named *Corynebacterium glutamicum*) in Japan in 1957 (Kinoshita) marked the beginning of a 40 year period of growth in high volume, fermentation derived bioproducts.

Monosodium Glutamate (MSG). Production of monosodium glutamate (MSG) via fermentation was not practiced until 1961. The discovery of the L-glutamic acid producer, *M. glutamicus* in 1957 (Hirose et al., Kinoshita) and the realization that a critical concentration of biotin (ca. 2 ppb), or biotin together with an antibiotic or non-ionic detergent, was needed to maximize L-glutamic acid production (Aiba et al., Hirose et al.), marks the transition of an amino acid industry based on processing of natural materials, to one dominated by fermentation based technology for production of food and feed additives, and products used in therapeutic applications. At about the same time, the first industrial production of another α-amino acid, L-lysine, was also initiated (DeGussa, 1985). By 1972, the world production of glutamate was 180,000 tons, of which 90% was made by fermentation (Aiba et al.), and by 1976, Japan produced two-thirds of the world's amino acids with an estimated annual sales value of $\$3 \times 10^9$ and a volume of 200,000 tons/year. Half of this volume was MSG, which was used almost exclusively as a food seasoning. A small

amount was employed in the production of a leather substitute (Hirose et al.). Just as is the case for antibiotics, some amino acids are produced by chemical synthesis. In particular DL-methionine, DL-alanine, and glycine are obtained via chemical synthesis.

The impact of glutamic acid bacteria on monosodium glutamate cost was dramatic. In 1950, MSG was obtained from natural products (i.e., soybean) and cost $4/kg. When the first fermentation process started up in 1961, the price dropped to $2/kg. By 1970 the price settled to about $1/kg, and in 1983 approximately 220,000 tons of MSG/year were being produced by fermentation, worldwide, with a sales value of about $\$550 \times 10^6$.

The discovery of glutamic acid bacteria resulted in a fundamental change in the industry, not only for MSG production, but also for other amino acids, which could now be obtained via fermentation. Mutation of glutamic acid bacteria with ultraviolet light, X-rays, γ-rays and chemicals resulted in amino acid producing auxotropic and regulatory mutants for the L-forms of lysine, threonine, tyrosine, phenylalanine, L-ornithine, proline, leucine, citrulline, and homoserine, as well as glutamic acid. The multiplicity of names given to glutamic acid bacteria discovered after 1957 was a source of confusion. Based on conventional taxonomy, and the 73 to 100% DNA homology reported for several strains of *Corynebacterium*, *Brevibacterium*, and *Microbacterium* in 1980, the glutamic acid bacteria were reasonably regarded as a single species in the genus *Corynebacterium* (Kinoshita).

Although MSG remains the single largest fermentation derived amino acid, there are a number of other valuable amino acids obtained from mutants or related microorganisms of the genus *Corynebacterium*. Lysine (an animal feed additive), is the second largest amino acid obtained by fermentation. It had a worldwide production of 40,000 tons/year in 1983 compared to MSG at 220,000 tons/year. More recent valuations place the worldwide lysine market at $\$600 \times 10^6$/year in 1996, with half of the sales attributed to Archer Daniels Midland. Some lysine producers also manufacture the carboxylic acid, citric acid, with annual sales of $\$1 \times 10^9$ in 1996. Citric acid is a widely used flavoring agent and acidulant in beverages (Kilman, 1996a,b). Most other amino acids are small volume (10 to 300 tons/year), high value products obtained by fermentation, microbial conversion of intermediates, or enzyme synthesis (Hirose et al.). Dominant suppliers of amino acids are Ajinomoto, Takeda, and Kyowa (in Japan) (Hacking) and Archer-Daniels Midland (abbreviated ADM) (Kilman 1996a,b). The corn milling division of Cargill, a privately owned company entered lysine production. A letter of intent with the German Company, Degussa, resulted in an agreement "to build a 165×10^6lb/year synthetic lysine production facility at Cargill's Blair, Nebraska complex," with production to begin in the second half of 1999. (Anonymous, 1997). The announcement stated that "Degussa says it is the world's leading supplier of methionine, and a leading supplier of threonine. Lysine, synthetically produced by corn-fed microorganisms, is used as an additive for feeds for hogs and poultry." The syntax of this announcement is almost as interesting as its content. The term "Synthesis," which has previously been associated with *in vitro* chemical methods, is now used to describe an *in vivo* microbial method. This gives an indication of how the distinction between chemistry and biotechnology as a means of production is becoming blurred.

Some amino acids are derived by chemical routes, or through enzyme synthesis and microbial production starting with an intermediate. The largest volume, chemically synthesized amino acid is DL-methionine (also an animal feed additive) which is obtained from propylene, hydrogen sulfide, methane, and ammonia (DeGussa, Tanner and Schmidtborn). Another major chemically synthesized amino acid is a glycine chemical building block which is an intermediate in the manufacture of Monsanto's herbicide, Round-up®. Round-up® was estimated to generate about $\$2.2 \times 10^9$ in sales in 1995, and sales were expected to continue to grow with the successful introduction of "Round-up ready" soybean seeds in 1996. Commercial quantities of these herbicide resistant seeds were planted in 1996 and generated sales of about $\$45 \times 10^6$. A survey of 1058 farmers (about 10% of the farmers who planted the seed) showed that 90% of those surveyed felt the product met or exceeded expectations (Fritsch). These seeds were genetically engineered by inserting a gene from petunia that confers herbicide resistance to soybean plants (Fritsch and Kilman). This allows the fields to be sprayed with the herbicide, thereby killing all other vegetation, followed by planting of soybean seeds. The soybeans are able to grow since they are not effected by the herbicides.

These examples illustrate some of the cross-over and cross-disciplinary characteristics of biotechnology when applied to a specialty chemical business.

By late 1996, Monsanto had planned to divide itself into two entities: Monsanto Life Sciences and a chemical entity (later given the name Solutia) (Reisch). This occurred within a year, during which Monsanto purchased a plant biotechnology company (Calgene) that held patents for improved fresh produce, cotton seeds, specialty industrial and edible oils (derived from seeds) and plant varieties (Anonymous, 1997). Based on analysis of 1995 sales, the life sciences products accounted for annual sales of $5.3 billion based on the major products of Round-up herbicide, Round-up-resistant soybeans, Bollguard® insect-protected cotton, Nutrasweet® sweetner, and prescription drugs for arthritis and insomnia.

The incorporation of the *Bacillus thuringiensis* gene into cotton (Bollguard®) enabled the cotton to produce proteins that are toxic to cotton bollworm and budworm. The first trials of the transgenic cotton were a qualified success (Thayer, 1997). Approximately 40% of the Bollguard planted fields had to be sprayed although only one to two pesticide applications were required compared with a more typical four to five. Cotton growers reported an average 7% improvement in yield, as well as reducing or avoiding the use of pesticides. The farmers reported a $33/acre cost advantage of Bollguard cotton compared with insecticide treated non-Bollguard cotton, after the technology licensing fee of $32/acre and supplemental pesticide applications were accounted for.

Approximately 3% of Texas' three million acres of cotton, and 60–70% of Alabama's five hundred thousand acres of cotton were planted with *Bacillus thuringiensis* cotton in 1996. The potential economic and environmental benefits are evident when the size of the annual US cotton harvest (9×10^9 pounds, worth about $\$7.2 \times 10^9$), and volume of insecticides ($\$400–500 \times 10^6$/year) is considered. Bollguard plantings for 1997 were estimated at 2.5 million acres out of 14 million acres of cotton (Thayer, 1997).

Prices and Volumes. The price of biotechnology products (including, in the example at hand: Vitamin B_{12}, cephalosporin, penicillin, lysine, xanthan, glutamic acid, citric acid, gluconic acid, lactic acid, ethanol, and high fructose syrup) decreases as the total sales volume increases, with the relationship between price and volume falling on a characteristic line when the data are plotted on a double log scale (Hacking). This type of plot, previously used for correlating the cost of thermoplastics to their volume, is relevant for biotechnology products according to Hacking. Although the price and volume data are from 1986, and there is scatter in the data, the plot illustrates the necessity of reducing production costs to achieve bulk sales. This is both a function of the technology which must be available if production costs are to be reduced, and market demand that would drive the production of larger volumes of the product. In the case of monosodium glutamate, technology enabled a reduction in cost, which in turn increased the volume used. The essential amino acid, Tryptophan, would find uses in animal feed, and therefore offer larger volume markets, if its price were to decrease from $100/kg to $10/kg (based on 1986 prices, per Hacking). The dramatic decrease in the cost of penicillin within 12 years after its introduction illustrates that the volume–price relationship will also affect a high value drug. Penicillin was a wonder-drug when first introduced in 1941–1945, but then decreased in price from $500/g in 1943 to $0.10/g by 1956 (Hacking) as advances in manufacturing technology, improvements in productivity and product concentration, ramp-up of its volume, and economics of scale drove the price down (Hacking). The production cost of penicillin, while not a key issue in 1945, is certainly an important factor now.

The economics that currently drive the biopharmaceutical industry may be different, although it is too early to tell. Large volume uses of biotherapeutic products have not yet developed since the industry is still starting-up, and has yet to reach a steady-state growth phase. While the costs of production for a high value therapeutic contribute as little as 10% to the overall price of the product, production economics are secondary only to the timeline of drug development, competitive pressures, and marketing issues normally associated with introduction of a new product.

Biochemical Engineers and Microbial Fermentation. Biochemical engineering was defined by Aiba, Humphrey and Millis, in 1973, as "conducting biological processes on an industrial scale, providing the link between biology and chemical engineering," with its heart being "the scale-up and management of cellular processes" (Aiba et al.). It was viewed as the interaction of two disciplines. The definition was extended by Bailey and Ollis in 1977 to encompass "the domain of microbial and enzyme processes, natural or artificial," including "wastewater treatment as well as industrial fermentation and enzyme utilization." Shuler and

Kangi described biochemical engineering as "the extension of chemical engineering principles to systems using a biological catalyst to bring about desired chemical transformations," and as being "subdivided into bioreaction engineering and bioseparations."

Challenges that a biochemical engineer faces are the prevention of contamination (sterility); control and promotion of microbial growth and productivity through media composition; control of growth conditions (pH, temperature, product precursors); and oxygen transfer (for aerobic fermentation). The engineer must devise efficient and robust methods for recovering, and purifying an often, unstable product. These same disciplines and skills apply to manufacture of products from organisms that form the basis of the biopharmaceuticals industry.

Growth of the Biopharmaceutical Industry

Traditional biotechnology is based on indirect methods of selecting, improving, and propagating organisms. Its transition to a new biotechnology, based on genetic engineering, could be interpreted as an abrupt change in technology when viewed from an historical (8000 year) perspective. Actually, the technological change in the industry followed an evolutionary path in both methodology and perceptions that occurred over a period of about 40 years. Microorganisms, cells, plants, and animals (collectively referred to as organisms) with enhanced characteristics for production of bioproducts and antibiotics have been selected, manipulated and improved since the beginning of the industry. Genetic structures have been purposely altered using mutagens or radiation, selective pressures, breeding, and strain improvement. The discovery and development of the structure and function of DNA over a period of a century, allowed genes to be identified, and traits to be correlated to an organism's characteristics. These findings advanced both the fundamental understanding and practical applications of organisms for generating bioproducts (food, beverages, medicines, and chemicals). The developments of recombinant technology, that now benefits the pharmaceutical industry was catalyzed by, or was "a direct result of generous governmental funding for basic biomedical research since World War II (Olsen)."

The discovery of enzymes that cut or ligate DNA at specific locations, and development of practical methods for achieving alterations in a cell's genetic make-up changed the field. These enzymes allowed genetic manipulations, and the determination of the effects of these alterations, to be achieved in a matter of months, rather than years or decades. In addition to rapidity, these methods could be carried out in a directed and rational manner, thereby allowing introduction of completely new traits by design, rather than by chance, into the host organisms. This gave rise to the expression, "genetic engineering," i.e., genes could now be engineered and altered in a predetermined manner to confer a specified end result.

U.S. government policy in the 1980s regarding limited partnerships in risky ventures may have encouraged start-ups. An estimated, 1000 biotechnology companies were formed during 1980 to 1990. The major product groups addressed by these companies were: (1) diagnostics (human and/or animal health); (2) therapeutics (human and/or animal health); (3) Ag-bio (plant genetics and/or microbial crop protectants; and (4) suppliers to the industry (according to a survey by the Arthur Young Company, Burrill, 1988). By 1996 this number increased to 1300, of which about 200 are public. The growth in the number of companies is appearing to level-off in the U.S. (Thayer, 1997a) while growth in the number of companies, internationally, was continuing at a rapid pace. For example, the number of Canadian biotechnology companies doubled over a three year period, reaching 224 by 1997, with combined revenues of $\$837 \times 10^6$ (Thayer, 1997a).

Sales of biotechnology products grew from zero in 1980 to $\$4 \times 10^9$ by 1991, and $\$25 \times 10^9$ by 1996 (NAS, Olsen), with about $\$15 \times 10^9$ due to biopharmaceutical products. Of this amount, about $\$10 \times 10^9$ was attributed to clearly identifiable biotechnology companies.

The projections and financial performance of the biotechnology industry does not uniformly coincide with companies that manufacture and sell biotechnology products. For example, Eli Lilly and Company and Novo Nordisk are major suppliers of biosynthetic human insulin derived from recombinant microorganisms, yet these companies are sometimes identified as drug or industrial enzyme companies, not biotechnology companies. Consequently, a complete accounting of their sales derived from recombinant technology may not be possible. The overall accounting of the industry has included plant biotechnology products from a major chemical company such as Monsanto, even though it did not become a biotechnology company until September 1, 1997 (Anonymous, 1997). The internally consistent comparison of revenues and earnings of specific sectors of the bioindustry for estimating growth over different time periods can be challenging as well since large consolidations of companies have occurred (see timeline after 1992 in Table 1). Hence, revenues will vary significantly and depend on a particular survey's definition of the biotechnology industry.

This is well within the projections made for growth rate in 1991, where market estimates (in 1991) placed sales of biopharmaceuticals, alone, at $\$8 \times 10^9$ within 10 years (Thayer, 1998). The analysis of these sales in the context of the growth potential of biopharmaceuticals is somewhat complicated since the effect of major pharmaceutical companies buying smaller biotechnology companies, and the merging of sales figures is difficult to place into categories. The adaptation of biotechnology as a means of production by some of the large and long-established chemical, agricultural, and food companies, further obscures the definition of a biotechnology company. Furthermore, a significant volume of pharmaceuticals is manufactured by chemical synthesis, and these are not considered to be biotechnology products.

This sector is expected to continue to show strong growth with 284 new biotechnology drugs under development in 1996 (Thayer, 1997a Anonymous, 1996). However, this is still an industry that is very much in its early growth phase. A complete set of earnings figures would show that only 10 out of the 1300 biotechnology companies reported profits in 1997. All the others had negative earnings as of the first half of 1997 (Thayer, 1997a). Nonetheless, the professional services firm of Ernst and Young, which had analyzed and reported on the biotechnology industry, annually, for more than 11 years, characterized the period between July 1, 1995 to June 30, 1996 as showing "stunning results" for the industry. This is based on sales of biotechnology-related products, which rose 16% to $\$10.8 \times 10^9$/yr.

Biotechnology products, as defined here, are products sold by the biotechnology companies and exclude many bioproducts sold by established pharmaceutical, food or chemical industries, even though these products are biotechnology related. While pharmaceutical companies report sales, the biotechnology companies report revenues, which includes sales as well as income received for services and contract research. This method of accounting helps the financial analysis of the industry to track the progress of companies clearly started up within the last 20 years with 80% of these started up since 1986. The distinction is clearly described by Burrill and Lee in 1991. "Biotech companies will transform traditional industries. Pharmaceutical companies will become biopharmaceutical companies, being themselves transformed as they partner with biotech companies, acquire biotech companies and their technologies, and marry traditional pharmaceutical R&D methodologies with biotechnology's understanding of cellular behavior." "... we will see emergence of bioagricultural, biochemical, and bioenergy companies. Biotech companies will continue to exist with traditional companies transformed through their partnership."

The top 10 recombinant drugs accounted for nearly $\$5 \times 10^9$ in sales and the top 16 had sales of about 6.8 billion (Thayer, 1996), as shown in Table 3. Product sales, revenues, research and development expenses, and market value increased significantly for the industry between 1991 through 1996 as shown in Table 4 (Thayer, 1997c), although the industry as a whole would show a negative earnings and a deferred profit margin. This is consistent with the characteristics of the "present phase" of the biotechnology industry's life cycle. See Fig. 1. As of the first half of 1997, six leading biotechnology companies dominated the earnings figures. The single major contributing company was Amgen ($\$201 \times 10^6$ earnings for the first half of 1997). The combination of Biochem Pharma, Biogen, Chiron, Genentech, and Genzyme contributed another $\$98 \times 10^6$. The remaining 24 firms of the top 30 combined for a net loss of $\$120 \times 10^6$. The accounting of costs helps to communicate the stage at which the industry finds itself. However, an understanding of the technology, and insights into potential applications and markets is needed if the industry's tremendous potential for growth is to be understood and windows of opportunity identified. This article attempts to provide a brief introduction to the possible importance of selected molecules. These will be given as examples during presentation of bioseparations and bioprocess engineering principles.

Published analyses of the revenues and earnings segregate the biotechnology industry from the large pharmaceutical companies, which also market biotechnology products but are not counted as part of the start-up biotechnology industry. Comparison of the pharmaceutical industry's earnings compared to the combined earnings of 30 major biotechnology

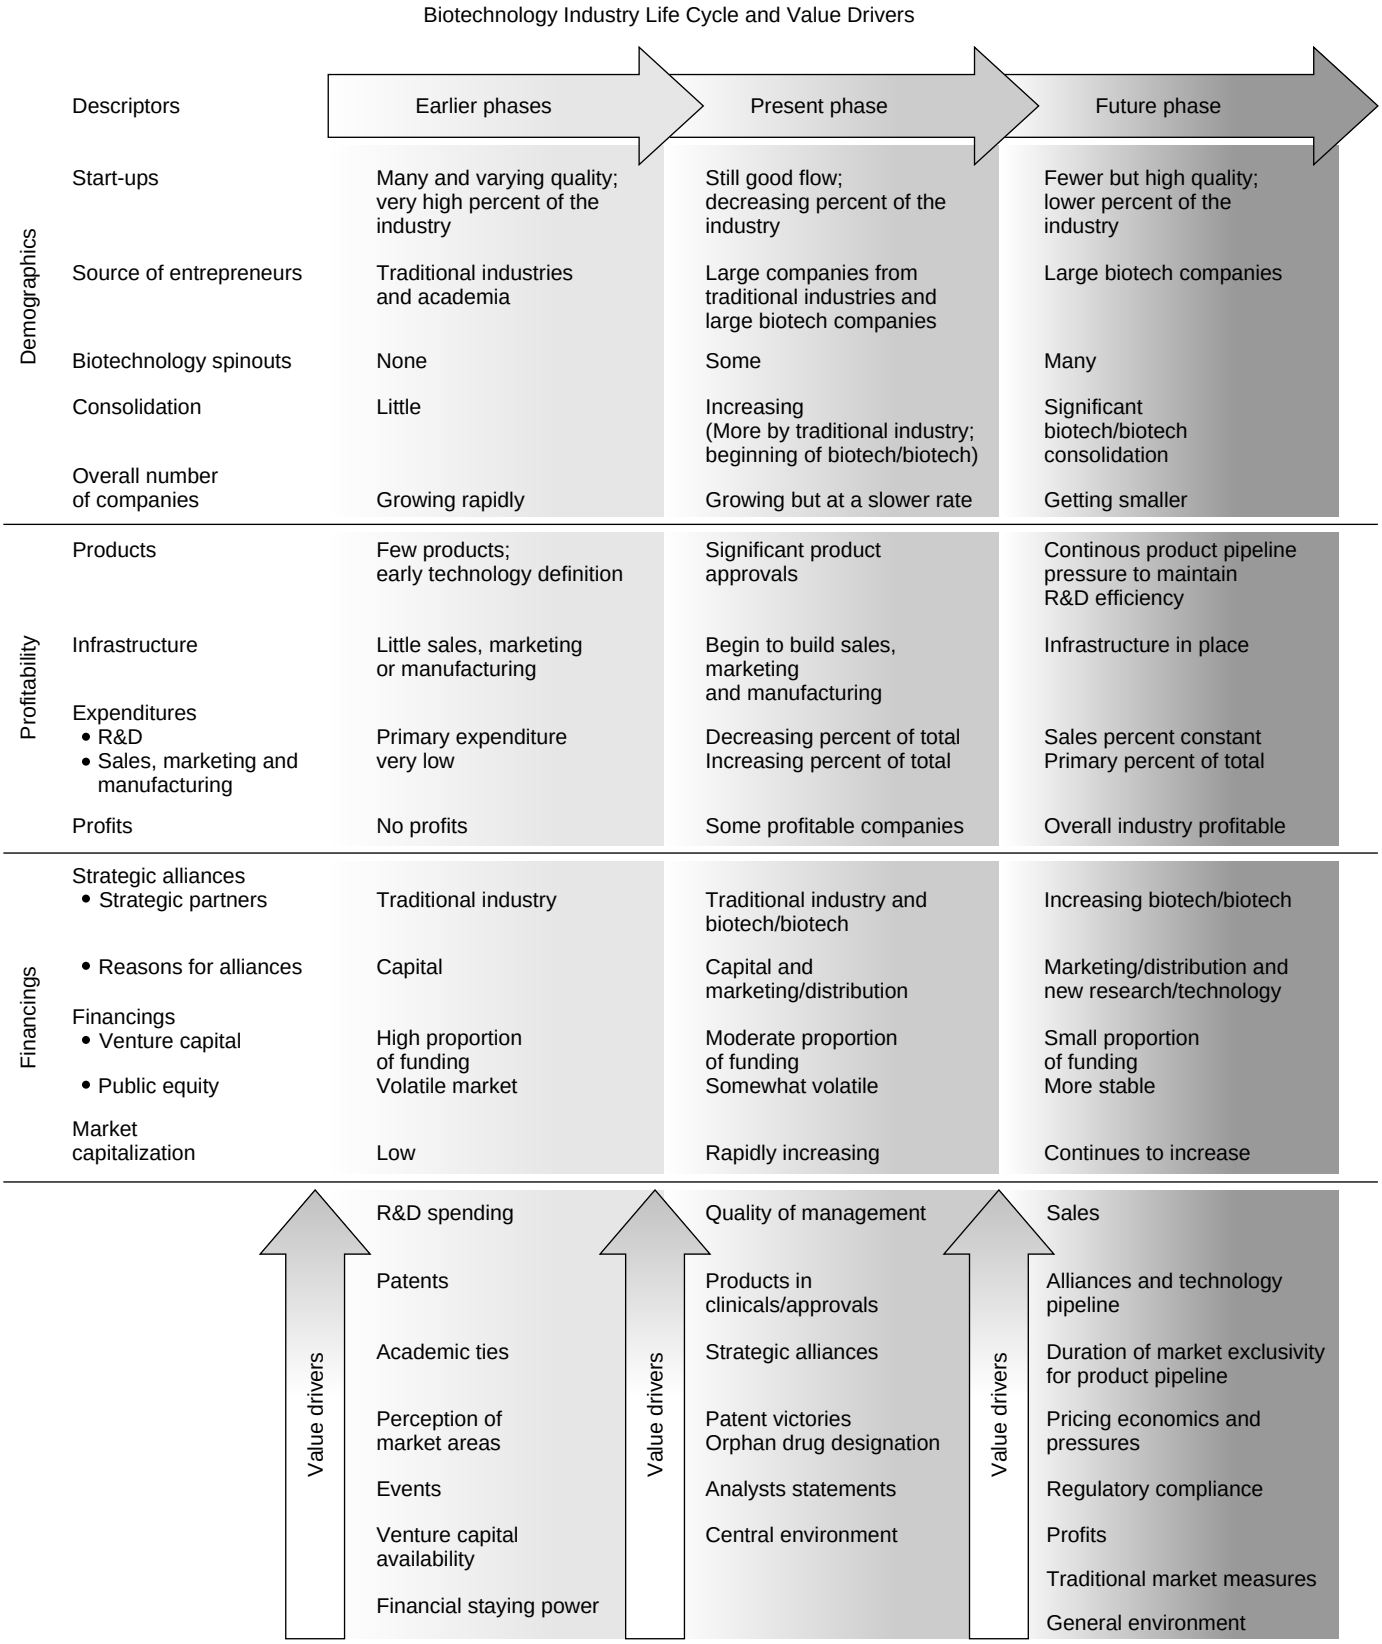

Fig. 1. Conceptual representation of biotechnology industry life cycle. The early phase coincides with period of approximately 1975 to 1990. The present phase started in about 1990 and is likely to continue through the beginning of the 21st century (figure from Burrill and Lee) [1991].

industries during the first half of 1997 illustrate the large differences in sales (revenues), earnings, and profit margins (see Table 5). The current pharmaceutical industry is much larger than the combined earnings of the 30 most significant biotechnology companies.

The biopharmaceutical industry is in the early part of its life cycle. The assessment of an industry doing well when it is losing money may seem unusual to a student in engineering or biological sciences. However, this is consistent with the start-up of an entire new sector of the economy, where negative cash flow during the beginning years of the individual companies cannot be offset until approved products reach the market and sales are generated. It is only in the later phase of the industry's life cycle that the overall industry becomes profitable.

TABLE 3. ANNUAL SALES OF MAJOR THERAPEUTIC BIOPHARMACEUTICALS TOP $\$6.8 \times 10^9$ IN 1995.[a]

Biopharmaceutical[a]	Disease	Annual Sales[b] ($ millions)
Anti-CD3 Mab (Monoclonal Antibody)	Transplant rejection	$80
Dnase	Cystic fibrosis	111
Erythropoietin	Anemia	1,650
Factor VIII	Hemophilia	250
GCSF (Granulocyte Colony Stimulating Factor)	Neutropenia	936
Glucocerebrosidase	Gaucher's disease	215[c]
GMCSF (Granulocyte Macrophage Colony Stimulating Factor)	Bone marrow transplant	41
GPIIb/IIIa Mab	Blood clots in angioplasty	130
Hepatitis B Vaccine	Hepatitis B	1,000
Human Growth Hormones	Growth deficiency, renal insufficiency	450
Insulin	Diabetes	700
Interleukin-2	Kidney cancer	40
α-Interferon	Cancers, hepatitis	700
β-Interferon	Multiple sclerosis	255
γ-Interferon	Granulomatous disease	4
Tissue Plasminogen Activator	Heart attack/embolism, stroke	300

TABLE 4. BIOTECHNOLOGY INDUSTRY SUMMARY: JULY 1 TO JUNE 30[a]

Values in $\$ \times 10^9$	1990–1991	1994–1995	1995–1996	% Change
Product sales	4.0	9.3	10.5	16
Revenues	5.8	12.7	14.6	15
Research and development expense	2.9	7.7	7.9	3
Net loss	10.9	4.6	4.5	−2
Market value		52.0	83.0	60
Number of companies (Industry total)	1,100	1,308	1,287	−2
Number of employees	70,000	108,000	118,000	9

[a] Adapted from Thayer based on data of Ernst & Young; 1990–1991 data from Burrill and Lee.

TABLE 5. COMPARISON OF THE BIOTECHNOLOGY AND PHARMACEUTICAL COMPANIES FIRST HALF SALES AND EARNINGS, 1997[a]

	Industry	
	First Half of 1997, All Pharmaceutical Companies	First half of 1997, 30 Major Biotechnology Companies
Sales (revenues), $\$ \times 10^9$	63.0	3.73
Earnings, $\$ \times 10^9$	11.0	0.269
Profit margin[b], %	17.3	7.2

[a] (From Thayer, (1997d)).
[b] After tax earnings as a percent of sales.

The key phases of the biotechnology industry's life cycle are schematically represented by Burrill and Lee. The data in Table 4 (for 1994–1995 and 1995–1996) are based on companies that were started up during the prior 10 to 15 years. All of them were at a similar stage of the product development cycle, and few had positive earnings at this point. This differs from an established industry where most companies have positive earnings, with only a few start-ups that might be experiencing a negative cash flow. The rapid changes between negative earnings and profitability can be illustrated by the earnings history of the six largest biotechnology companies with acquisitions and restructuring contributing to the volatility. The biotechnology industry, while risky, also has an enormous earnings potential. Hence, there are investors willing to risk capital to get the industry started.

The importance of new developments is often difficult to gauge at times relatively close to their discovery. Nonetheless, it would appear that an important transition occurred approximately 45 years after the discovery of penicillin, and 30 years after its first large scale manufacture through submerged fermentation. The first therapeutics, were microbial substances made by microbes for activity against other microorganisms. Biologically active proteins, referred to as biopharmaceuticals, were made possible by advances in molecular biology since microorganisms could now express mammalian proteins having therapeutic use. Perhaps more importantly, molecular biology and genetic techniques have made it practical to discover new knowledge about how biological systems function, and how various molecules, not just proteins, moderate the biological chemistry of living cells. New types of therapeutic approaches are made practical by this expanded knowledge of biological systems. The means by which molecules for therapeutic use are manufactured may prove to be a key technological shift that differentiates the current fermentation and pharmaceutical industry from the nascent biotechnology industry.

Discovery of Type II Restriction Endonucleases. In 1970, Kelly and Smith, and Smith and Wilcox, discovered enzymes, known as Type II restriction endonucleases, which recognize a particular target sequence in duplex DNA. This enabled use of the enzyme to obtain discrete DNA fragments of defined length and sequence, and therefore facilitate a key step in carrying out genetic engineering (Old and Primrose). Unlike mutation and screening procedures, genetic engineering entails insertion of a foreign gene into the genetic material of a microbial cell, so that the cell can produce proteins that would otherwise not be found in the cell. The impact and commercial possibilities of this technique are credited to Cohen, Chang, and Boyer, who in 1974, established practical utility of constructing biologically functional plasmids *in vitro* and transforming *E. coli* to express foreign protein (Ryu and Lee, MacQuitty). The basis of the technique is illustrated in Figure 2.

Kohler and Milstein are responsible for the third significant development during this time. In 1975 they demonstrated that cells derived from mouse *B lymphocytes*, which secrete antibodies, were fused with mouse myeloma tumor cells from a mouse, which can grow indefinitely in culture (see Fig. 3). The resulting fused cell, is a *hybrid-myeloma* or hybridoma cell that can grow in cell culture and produce large quantities of chemically identical antibodies, i.e., monoclonal antibodies, which are excellent probes for diagnostic purposes (Olsen) and are being developed for possible use as a drug delivery system (see Fig. 4).

The restriction enzymes and hybridomas enabled new types of pharmaceutical products The developments associated with restriction enzymes (facilitate genetic engineering) and hybridomas (produce monoclonal antibodies) opened up vistas for a new range of potential products. Isolated from humans directly, these can now be produced in microorganisms or cell culture, and be used in large concentrations to enhance the body's ability to fight heart disease, cancer, and viral infections against which most antibiotics have little or no effect.

Regulatory Issues. A new drug must move through three stages of testing and review, adding to the time required to bring a new drug to market. These stages follow an investigational new drug (IND) application (Thayer, 1991):

Phase I Clinical Trials: Safety and pharmacological activity of a drug is established using 100 or less, healthy human volunteers. These require about one year;

Phase II Chemical Trials: Controlled studies are carried out on 200 to 300 volunteer patients to test drug efficacy together with animal and human studies for safety. This stage requires about two years.

Phase III Clinical Trials: Efficacy results are confirmed using about 10 times more patients than used in Phase II trials. Low-incidence adverse effects are also identified. This phase requires about three years.

A product license application is then filed with the FDA, which had required about two to two and one half years to review up until 1993, when efforts were undertaken to reduce the time required. Now, some approvals can now be achieved in 15 months. Thus, if approved, a new product may require up to 7 to 10 years to pass from preclinical trials to commercial introduction. This process, for one new drug, is estimated to cost at least

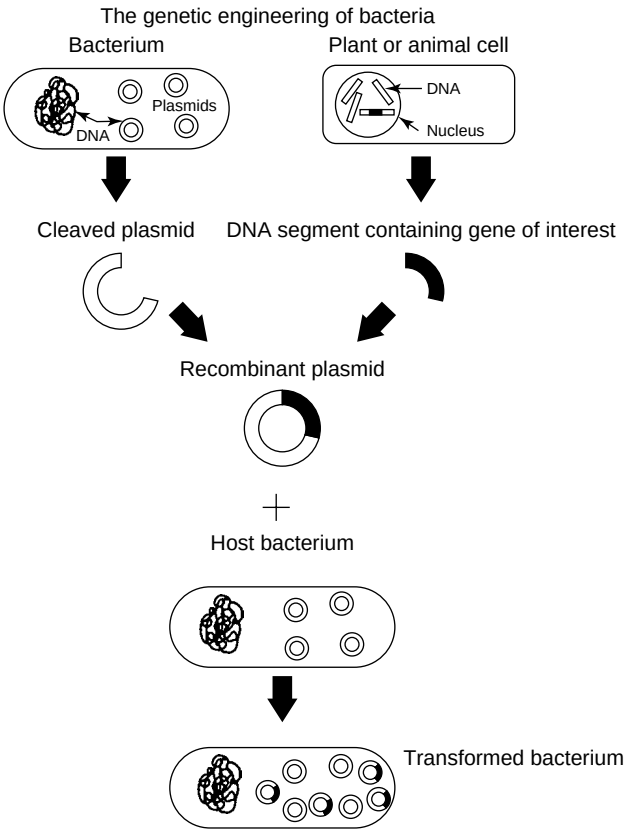

Fig. 2. One common way to genetically engineer bacteria involves the use of small, independently replicating loops of DNA known as plasmids. Certain enzymes can cleave these plasmids at specific sequences in their genetic codes. DNA from other organisms that has been treated with the same enzymes can then be spliced into the plasmids with enzymes that join the cut ends of DNA. These recombinant plasmids are reinserted into bacteria, where they can reproduce themselves many times over. At the same time, the bacteria can divide, creating millions of copies of the introduced DNA. This DNA can then be studied through analytical techniques, or, if a gene within the introduced DNA can be made to produce the same protein it did in its original location, the genetically engineered bacteria can be used as microbial factories to make large quantities of the protein (reprinted with permission from Olsen, 1986, p. 17, Copyright National Academy Press).

$\$120 \times 10^6$ and as much as $\$240 \times 10^6$. For serious or life-threatening diseases, promising Phase I results can lead to combined Phase II and Phase III trials, thus reducing the time by two or three years. The approval process is thorough, lengthy, and expensive. Bioprocess engineering plays a key role in quickly developing means of production for supplying the needed amounts of pure material required for these trials. In this case, the scale-up of production must follow a time-scale that is less than that required for each of the trials. Otherwise, completion of the trials can be delayed due to a shortage of the drug being tested.

The challenge for bioprocess engineers transcends scale-up issues and the drive for a company to be the first to market. As articulated by Bailey and Ollis, "... modifications in the organism or in the process require some degree of reiteration of earlier tests, or re-examination of the system by regulatory authorities. Therefore, a premium exists for engineering strategies that provide effective *a priori* guidance ... in organism, product, and process development." Because of the associated regulatory costs, incremental process improvements may not be commercially significant until relatively late in the product life cycle, when there are several suppliers and competition for a given drug develops. A similar analysis was also presented by Wheelwright (1991) in the context of purifying proteins in a commercial setting.

Reduction in the time and expense for approving new biopharmaceuticals may accelerate development of new products and processes. The increase in the number of new biotechnology drugs and other products that are subject to review and approval by the FDA coincided with changes at the FDA starting in about 1990. Practices were initiated to decrease the amount of time between development of a new drug or biologic and its approval. A concurrent process was instituted to move safe, efficacious drugs, that were not fully tested, to terminally ill patients (Ember). However, for many new pharmaceuticals, a key issue was the length of time required for the review process which, in 1993, required about 30 months. By 1996, the time was reduced to 15 months (Stone). Only 15 biotechnology drugs had been approved from 1983 to 1992 year period. However, there were approximately 300 products in clinical trials in 1992. Many of these were likely to reach the FDA for review (Ember). Consequently, the review process needed to be handled more quickly.

Fifty additional reviewers (for a total of 250) and the appointment of Kathryn C. Zoon, as a new director for the Center for Biologics Evaluation and Research, occurred in 1992, under the leadership of FDA commissioner David Kessler, despite the lack of additional funding for the FDA to carry this out (Ember). By 1996, 500 new scientific staff (from microbiologists to statisticians) had been hired to review applications. The funds for the additional staffing resulted from authorization by Congress for the FDA to collect user fees from the industry.

The effect of user fees, and the additional staff that it enabled, was a reduction in the time required to process a new drug application. It was 30 months in 1992 and 17 months in 1995, with 15 months projected for 1996. Furthermore, the time required for anticancer and AIDS drugs was as little as six months. There were still industry complaints, however, that FDA reviewers would often ask for additional, time-consuming tests during the later part of the review process, thereby causing extra research and development expenses. Overall costs for developing, producing, and testing a new drug was estimated to be $\$500 \times 10^6$ in 1996 (Stone).

The renewal of the user fee arrangement for an additional five years by the U.S. Congress in November 1997, was viewed as "landmark legislation that codifies many new FDA regulations, revises its policies, and updates a number of outmoded practices. The bill also reauthorizes the Prescription Drug User Fee Act (abbreviated PDUFA) for another five years, an objective that pushed the entire package through the legislative labyrinth (Wechsler)". Some key provisions, other than user-fee contributions from the pharmaceutical industry, were fast-track approval of critical drugs; expanded access to investigational therapies for patients with AIDS, cancer, and other serious diseases; and six months of additional exclusivity for manufacturers that conduct pediatric studies for new or approved drugs or manufacturers that develop new antibiotics.

Another key provision could encourage, as well as speed-up, development of new biopharmaceuticals. The FDA may now approve a new drug or biotech therapy based on pilot or small-scale manufacturing data. Preapproval requirements were reduced for certain post-approval manufacturing changes for drugs and biologics (Wechsler). Although the regulations on these policies would require another two years (until 1999) to be published (Wechsler), one implication was that some types of biologics (such as recombinant vaccines) derived through recombinant organisms or recombinant technology might be regulated more like drugs. Another practical effect may be that test quantities of new recombinant protein products can be produced in a facility other than the one used for full-scale production. Previously a manufacturing facility would be built (before the product was approved) to produce test lots of a new product. It may soon be possible to contract out manufacture of the product (to an existing facility), rather than build a new plant in-house. A new plant, based on an untested product, had previously been required due to the constraints of the FDA approval process. This is very expensive and inhibited product development, since such a plant would face a risk of being "moth-balled" if clinical trials were unsuccessful. While the equipment in such a facility could be used elsewhere, the investment in engineering, systems design, process control, and investor's capital would be lost. Changes in the guidelines would ease this restriction on many types (but not all) biotechnology products. A facility designed specifically for manufacturing the product would not need to be built before the product is approved. This could reduce the time and expense of introducing a new product, as well as moderate the risk of developing a new product.

The goal of the FDA is to reduce the time needed to review and act on new drug applications, product and biologic license applications, efficacy and manufacturing supplements, and resubmissions. According to the synopsis given by Wechsler in November, 1997 (Wechsler): "the agency's goal will be to review and act on 90% of standard submissions and efficacy supplements within 10 months of receipt, priority submissions

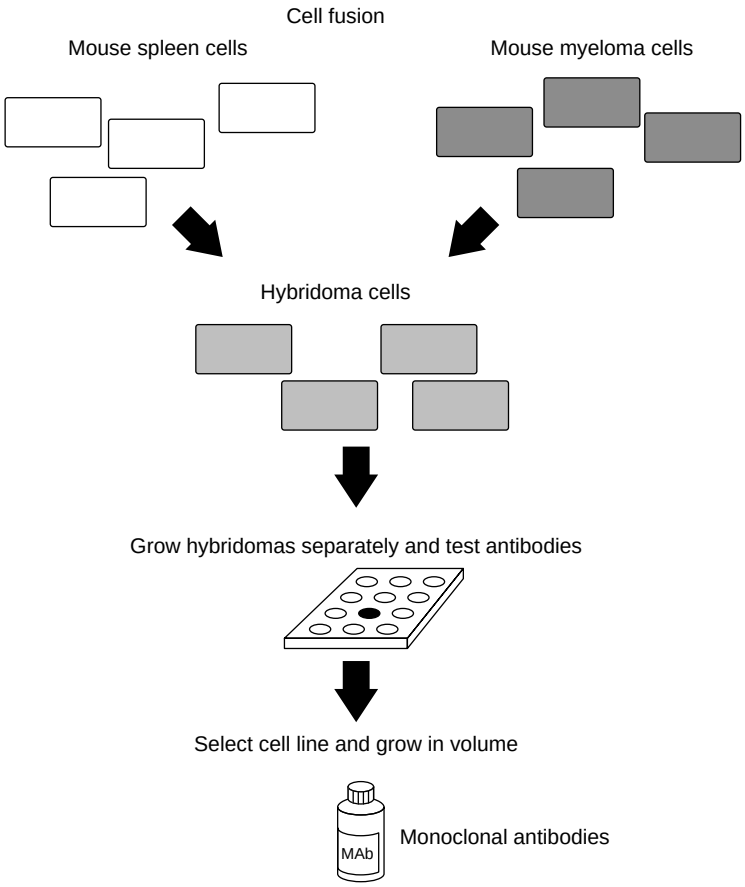

Fig. 3. To produce monoclonal antibodies, antibody-producing spleen cells from a mouse that has been immunized against an antigen are mixed with mouse myeloma cells. Under the proper conditions, pairs of the cells fuse to form antibody-producing hybrid-myeloma ("hybridoma") cells, which can live indefinitely in culture. Individual hybridomas are grown in separate wells, and the antibodies they produce are tested against the antigen. When an effective cell line is identified, it is grown either in culture or in the body cavities of mice to produce large quantities of chemically identical, monoclonal antibodies (reprinted with permission from Olsen, 1986, p. 26, Copyright, National Academy Press).

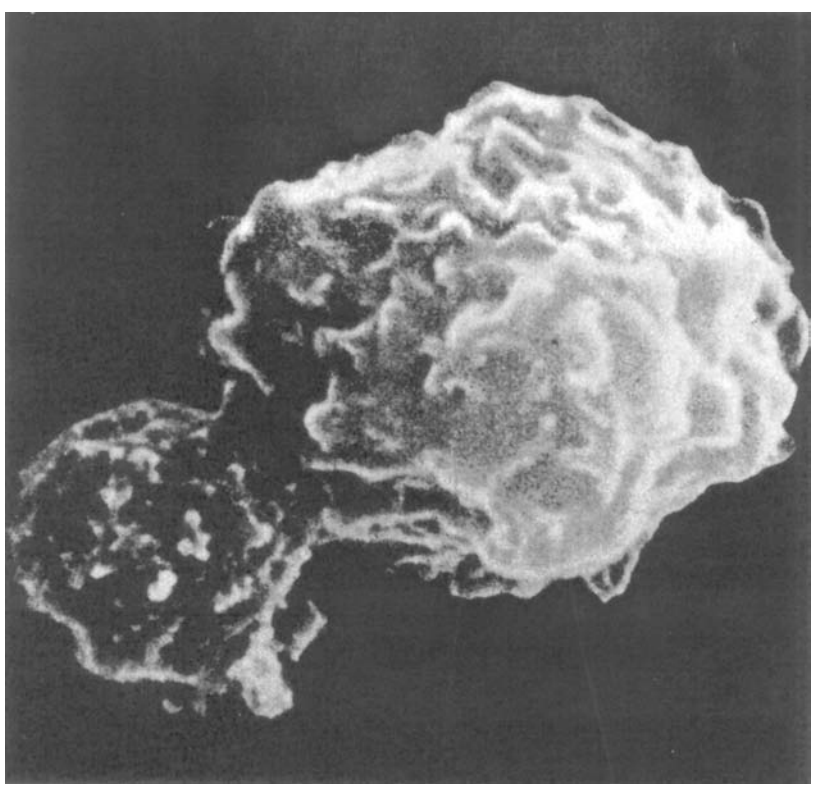

Hybritech

Fig. 4. A mouse spleen cell and tumor cell fuse to form a hybridoma. As the hybridoma divides, it gives rise to a "clone" of identical cells, giving the name "monoclonal" to the antibodies those cells produce (reprinted with permission from Olsen, 1986, p. 27, Copyright, National Academy Press).

and efficacy supplements within 6 months, manufacturing supplements within 4–6 months, and resubmissions within 2–4 months." The practical consequence of these modernized policies and shorter turn around time for supplements may be to promote development and installation of process improvements. This should have a positive effect on the development on new types of bioseparations for both new and existing products, where overall purification costs account for 50 to 90% of manufacturing costs. This change in regulation should create opportunities for bioprocess engineers, conversant in bioseparations, to invent, develop, design, and operate improved purification processes that cost less.

Growth of Industrial Enzymes

Catalysis in biotechnology, biocatalysis, has traditionally been associated with enzymes. At first glance the enzyme market would appear to be large at $\$650 \times 10^6$ (worldwide) in 1996. About 40% of the enzymes are used in detergents, 25% in starch conversion, and 19% in the dairy (cheese) industry. Consequently only a small fraction of the enzymes are employed as catalysts in reactions other than hydrolysis of starches (amylases) protein (proteases), and milk (chymosin and related proteases) (Layman). An example of how the new biotechnology has affected the enzyme business is given by the production of the milk clotting enzyme, chymosin, through a recombinant yeast, and improving cellulase enzyme titers in fungal fermentations. The recombinant chymosin is in commercial use in the dairy industry, where it supplants an enzyme previously derived from an animal source. Cellulase enzyme systems have been used in the clarification of citrus juices, and more recently to impart a "stone-washed" appearance to cotton fabrics by limited hydrolysis of the cellulose containing cotton fabric (Tyndall). These are derived from fermentation of recombinant microorganisms. Technology for cost-effectively converting cellulosic wastes to fermentable sugars could some day be enabled by application of cellulase enzymes, and thereby create a very large market for these enzymes. In the interim, a number of smaller, specialty niches will make up the demand for these enzymes, although the impact of such products in processing bulk agricultural commodities into value-added products should not be overlooked.

Glucose Isomerase and Sugar Production from Corn. Glucose isomerase is an example of an enzyme that catalyzed the development of a new industry, as well as the isomerization reaction for converting glucose (from starch) into fructose. Fructose containing corn syrups had grown to 17×10^9 pounds/year in 1991, worldwide, since being introduced in 1967 and 21×10^9 pounds in the U.S. in 1997 (Corn Refiners Assoc., Lastick and Spencer). The industry is based on an enzyme known as glucose isomerase that catalyzes the conversion of glucose (dextrose) to its chemical isomer (fructose). The equilibrium mixture of glucose with 42% fructose has a sweetness which approaches that of sugar derived from sucrose (cane sugar). Development of large-scale separation technology for partially separating glucose from fructose to give a product with 55% fructose, enabled this sugar to be used in consumer products ranging from soft drinks to donuts. Since the glucose was derived from corn, which is a less expensive agricultural commodity than sucrose from sugar cane, high fructose corn syrups displaced sucrose in the majority of high volume applications. The applications had previously been based on sucrose that had been hydrolyzed to glucose and fructose to obtain the same level of sweetness as high fructose corn syrup.

Glucose isomerase was initially isolated and identified in 1953 as a xylose isomerase (Hochester and Watson). Four years later the glucose isomerizing capability of xylose isomerase from *Pseudomonas hydrophilia* was discovered although arsenate was required to enhance the reaction. This enzyme was thus impractical for food production (Marshall and Kooi).

A key development for commercial prospects occurred in 1961, when it was found that not all glucose isomerases required arsenate, and that at least one of the arsenate requiring enzymes was in fact a glucose phosphate isomerase which converted glucose-6-phosphate to fructose-6-phosphate. While *Escherichia intermedia* had glucose phosphate isomerase (Natake and Yoshimura, Natake 1966, 1968) several other organisms (*Lactobacillus brevis*, *Aerobacter cloacae*, and *Streptomyces phaeochromogenus*) yielded isomerases, which did not require arsenate (Yamanaka, Tsumura and Sato, 1965a,b, 1970). Glucose and xylose isomerase activities were proposed to be due to the same enzyme (Yamanaka 1963b, 1968). Evaluation of the activities of a highly purified crystallized glucose isomerase from *Bacillus coagulans* was consistent with this hypothesis (Danno). It has been suggested that two enzymes, xylose isomerase (requires xylose as an inducer, but no arsenate), and glucose phosphate isomerase (does not require xylose as an inducer, but needs arsenate for activity) were co-purified in the early work, hence giving the observed properties (Tsumura et al. 1967).

The identification of a thermally stable glucose isomerase and an inexpensive inducer was needed for an industrial process. The discovery of enzyme from *S. phaeochromogenus*, which was thermally stable at 90 °C in the presence of substrate and Co^{++} (Tsumura and Sato 1965a,b, Tsumura et al. 1967), was important to setting the stage for commercialization. A thermally stable enzyme reduces cost by increasing its useful lifetime, and therefore, its overall productivity. The last major barrier to large-scale production of the enzyme was replacement of the expensive xylose media on which *S. phaeochromogenus* had to be grown to obtain glucose (xylose) isomerase enzyme, with a less expensive carbohydrate source. This turned out to be xylan containing wheat bran, corn bran, and corn hull (Takasaki, Takasaki et al.). Later it was found that D-xylose could induce glucose isomerase activity in *Bacillus coagulans* cells previously grown on glucose (Danno). The stage was now set for a new biocatalyst to transform the corn wet-milling industry.

The demand for high fructose corn syrup (HFCS) resulted in large scale use of immobilized enzymes and liquid chromatography. In 1965–1966, Clinton Corn Processing Company of Iowa (at that time a division of Standard Brands, Inc.) entered into an agreement with the Japanese government to develop the glucose isomerase technology for commercial use in the U.S. (Tsumura et al., Lloyd and Horvath). The glucose isomerase was really a xylose isomerase derived from *Streptomyces rubiginosus* and had the properties of thermal stability and high activity which made it amenable for use at industrially relevant conditions for use in batch reactions. The first enzymatically produced fructose corn syrup, was shipped by Clinton Corn in 1967. A.E. Staley licensed the technology from Clinton Corn and entered the market.

The basic patent coverage for use of xylose isomerase to convert glucose to fructose was lost in 1975 as the result of a civil action suit between CPC International and Standard Brands. This enabled development of alternate processes. By 1978, the estimated US production volume was 3.5×10^9 lb and consisted mostly of syrups containing 42% D-fructose sold at a 71% solids level (Antrim et al.). The introduction of large scale liquid chromatographic purification of the fructose enabled production of a 55% fructose which could be used in soft drinks in place of invert from sucrose.

The growth of the industry both promoted and followed development of large-scale technologies for carrying out the conversion in reactors packed with immobilized glucose isomerase, and large-scale liquid-chromatographic separations of the resulting sugars. Immobilized enzyme technology took advantage of the heat stability of the glucose isomerase by fixing the enzyme within, or on the surface of, solid particles. These particles, when packed in large vessels, enabled the enzyme, which was otherwise water soluble, to be held immobile while the glucose solution (at concentrations of up to 40% solids) was passed through the reactor. This made it possible to continuously process an aqueous glucose solution by passing it through a fixed bed, biocatalytic reactor to convert it to fructose. However, equilibrium limited the conversion to 42% fructose. Large-scale liquid chromatography was therefore needed to upgrade the 42% fructose directly obtainable from enzyme conversion, to the 55% required for sweetness equivalent to invert (a hydrolyzed form of sucrose). Liquid-chromatographic separations technology (Sorbex) for continuous sorptive separation of xylenes in a simulated moving bed was adapted to glucose/fructose separation by UOP to give the SAREX process for enriching the fructose content. Part of the effluent from the immobilized enzyme reactor is diverted to the chromatography column. The glucose-rich stream can be recycled to the immobilized bed reactor to be converted to 42% fructose, as shown in Figure 5. The stream high in fructose is mixed with the remaining 42% fructose stream to give the 55% product. The combination of an enzyme reaction with separation made the 55% HFCS product economically and technically feasible in about 1975. Subsequently, HFCS −42% and −55% syrups gradually displaced sucrose for commercially produced beverages and baked products.

Rapid growth of HFCS market share was enabled by large-scale liquid chromatography and propelled by record high sugar prices. The "Pepsi" taste challenge showed consumers preferred soft drinks that were made from 55% HFCS compared to a competing product made from sucrose.

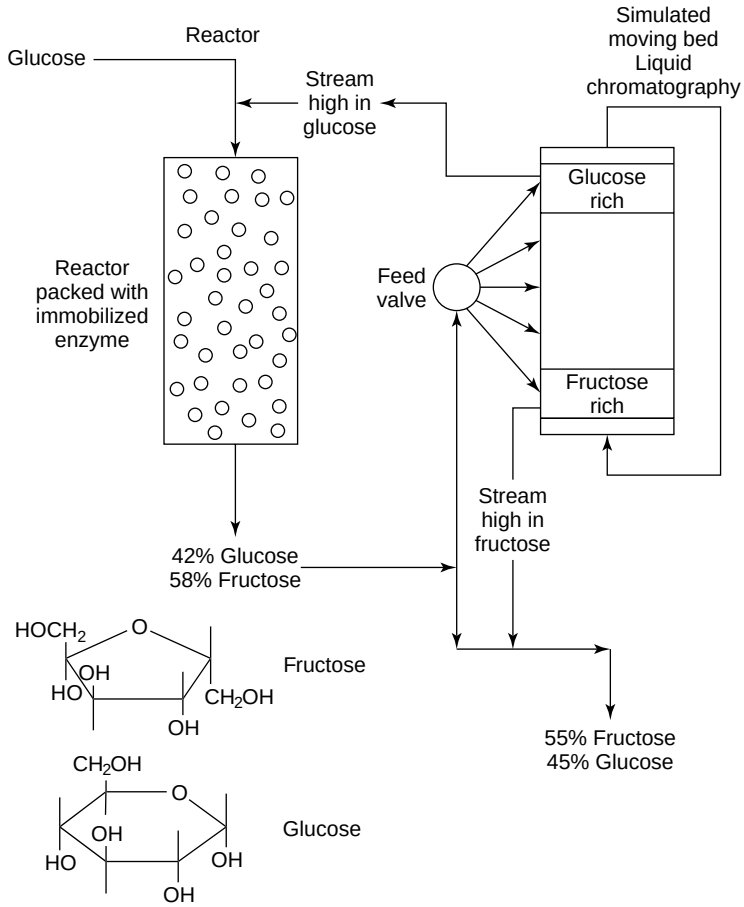

Fig. 5. Schematic diagram of combined immobilized enzyme reactor and simulated moving bed chromatography for producing 55% HFCS. The immobilized reactor is filled with pellets or particles in which the glucose isomerase is either entrapped or attached. Glucose solution, which also contains ions required for enzyme activity and about 3% residual soluble starch fragments (maltodextrins). The glucose feed is passed through the reactor, which is maintained at 50 to 60 °C. The immobilized enzyme converts the glucose to fructose. The product leaving the reactor contains about 42% fructose as well as the other ions and maltodextrins that do not react. The composition shown in the figure is normalized for the total glucose and fructose content, and does not reflect other dissolved solids. The effluent from the reactor enters a very large liquid chromatography column, packed with an adsorbent that selectively, but weakly, retains the fructose over glucose. The 42% fructose feed is introduced to different parts of the column in a time varying manner, through a special feed valve, in a manner that simulates a moving bed, so that the use of adsorbent is maximized. Sections of the bed that are rich in glucose and fructose are formed and maintained a steady state operation. This system allows a feed of 42% fructose to be continuously separated. The glucose that is separated out is returned to the reactor so that it will be converted to fructose.

Large-scale liquid chromatography made it possible to upgrade the high fructose corn syrups from 42% fructose to 55% fructose. By 1984, the 42% and 55% syrups exceeded 8×10^9 pounds annually, and accounted for 30% of all nutritive sweeteners in the U.S. (Lloyd and Horvath). The 55% fructose was quickly displacing industrial sugars previously derived from sucrose and accounted for over 50% of the HFCS shipped in the US in 1984. By 1990 the world market for HFCS had grown to about 17×10^9 lb/yr (Lastick and Spencer). The U.S. production of high fructose corn syrup − 42% (denotes 42% fructose) was 8.57×10^9 lb pounds while high fructose corn syrup − 55% + was 12.5×10^9 lb for a total of 21×10^9 in 1997 (Corn Refiners Assoc.). The value of the xylose (glucose) isomerase enzyme used in these processes is estimated at between $\$15 \times 10^6$ (Lastick and Spencer) to $\$70 \times 10^6$ dollars/yr. (Petsko), with most glucose isomerase being produced for captive or contract use.

The rapid adaption of the combined enzyme reactor/product separation technology in the wet milling industry coincided with dramatic, but short-lived, increases in world sugar (sucrose) prices. The demand for industrial sugars exceeded the supply. This short fall not only raised prices, but also provided a window of opportunity for a competing product, HFCS, to enter the market. The properties of HFCS were the same as dissolved invert (from sucrose) in applications where sucrose would otherwise be used. The cost was less. By positioning the price of the HFCS slightly below that of sucrose (invert), HFCS producers were able to retain market share. When the prices increased by extraordinary values, the price of HFCS was about double of its cost of production. Consequently, investments in building new plants were quickly paid off, making further rounds of expansion possible, and further entrenching the competing product in the market. This is not typical of other biotechnology products, where higher prices are based on a unique product, protected by a patent.

Stabilization Sugar Prices. Immobilized enzymes and large scale liquid chromatography may have helped to stabilize sugar prices. Sugar prices are among the most unstable prices in international trade. World sugar price spikes were characterized by a pattern of high prices for one or two years followed by five to ten years of low prices. The price instability reflects the relatively small share of the world sugar production that is freely traded. Thus world crop changes and shifts in government sugar policies exert a disproportionate effect. The inability for sugar producers to adjust output rapidly in response to changing economic conditions helped to propagate this cycle. The delay between planting and harvesting is eight months for sugar beets and up to two years for sugar cane. Consequently, increases in production capacity during the high-price phase of the sugar cycle would take several seasons to be absorbed by a relatively steady, but slow, increase in consumption. High prices also promoted expansion or construction of new plants to process the sugars. As explained in the Agriculture Information Bulletin No. 478 (Petrides et al.), "Processing facilities are expensive to construct. They require large size to capture scale economies. Consequently once a plant is in place, there is a strong incentive for the plans to be fully utilized to spread out fixed costs. After five to ten years of low prices and slow growth in consumption, world sugar production typically catches up with processing capacity. At this point, a disruption to production triggers an explosive price rise, and the sugar cycle begins a new"(Petrides et al.).

This cycle has occurred five times: 1950−1951, 1957, 1963−1964, 1974−1975, and 1980−1981 (Barry et al.). Domestic (U.S.) sugar prices

were also higher than the world price during several periods of low prices due to government policies. The major price surges of 1979/80 and 1980/81 resulted from bad weather in the USSR, India and Thailand; crop disease in Cuba; and reduced sugarcane acreage in Brazil. These periods coincided with major installation of plants for converting corn to high fructose corn syrup, with immobilized enzyme technology available in 1975, and combined enzyme conversion/liquid chromatography units being introduced in about 1977. Rapid payback of the capital investment was possible since the high world sugar prices helped to support the price of HFCS (Barry et al.). The technical ability to substitute HFCS for sugar in a wide range of products also promoted demand. The cost of production of HFCS, including normal returns on capital was estimated to be about 14/lb dry basis (Barry et al.) (This estimate, is based on costs of 4/lb net starch (equivalent to $2.60/bushel). The relatively low net starch costs are due to the value of corn wet milling by-products of oil, gluten feed and meal, with by-product values paying for approximately half of the corn costs. During the 1980s, enzyme costs also decreased, the scale of production increased, and the by-products enabled the plants to be fully utilized.) The lower production cost enabled the HFCS to be priced strategically below refined sugar prices. The prices of HFCS followed changes in sugar prices, but at a 10 to 30% discount. By 1989, HFCS had captured about half of the sugar market (Barry et al.).

Although per capita (U.S.) consumption increased to 130 lb of sugars/year, the price spike behavior was moderated. The acceptance of starch-derived and low-caloric sweeteners being widely accepted as sugar substitutes was a factor. The introduction of Aspartame, in 1981, and several other low-calorie, high intensity sweeteners coincided with a significant increase in the U.S. per capita consumption of low-calorie sweeteners, with low-calorie sweetener use being equivalent to 20 lb per capita in sugar-sweetness-equivalent (SSE). In 1980, this was about 6% of the total sugar consumption compared to 13% in 1988. Consequently, starch-based sweeteners, and to a less extent-low caloric sweeteners, are poised to take advantage of sugar shortfalls and high-prices, should they occur (Barry et al.). The recent history of sugar prices illustrates the complexity interactions between technology, commodity prices, and market demand for a product derived from renewable resources.

Cost-effective Enzymes. Submerged fermentation was the key to obtaining cost effective enzymes. As was the case for penicillin, success in submerged fermentation of microbes that produced the intracellular enzyme glucose isomerase was a key step in obtaining a cost-effective enzyme. When combined with development of processes for utilizing the enzyme at a commercial scale and an economic separation technology, a new product resulted. HFCS grew from zero to 17×10^9 lb annually (worldwide) in less than 25 years. The enzyme glucose isomerase also set the stage for the U.S. fuel alcohol industry, since the major HFCS producing companies had the infrastructure and large-scale processing know-how to establish it. The fermentation ethanol industry grew from about 100×10^6 gal in 1980 to over 1.5×10^9 gal/year in 1997.

Biocatalysts Used in Fine Chemical Manufacture. Although the total U.S. enzyme market in the mid-1990s was about $\$650 \times 10^6$ dollars/year, only about 5% was for biocatalysts used in fine chemical manufacture. The main biocatalysts were hydantoinase, β-lactamases, acylases/esterases, and steroid transforming enzymes (Polastro et al.). The discovery and development of catalytic antibodies may expand the role of biocatalysts, since this type of biocatalyst combines specificity of binding of an antibody together with the ability to transform a target molecule chemically. Hybridoma technology allows generation of antibodies to haptens or stabilized transition state analogues that have catalytic side chains in an antibody combining site. Hybridoma technology facilitates synthesis of gram quantities of the catalysts with very high specificity, compared to years required by other design and organic synthesis approaches. Catalysis using these types of antibodies are likely to occur since the antibodies are able to catalyze a large number of different reactions, including at least one type (Diels-Alder) for which an enzyme has yet to be isolated (Schultz et al.).

Enzymes in low-water environments can carry out selective transesterification reactions. Examples in the literature include polymerization of phenols in an organic solvent, and the formation of the biodegradable polymer sucrose polyester (Ryu et al., Patil et al.). This is currently a developing field, but holds promise of applications in organic synthesis, since some enzymes have been shown to be active in organic solvents. Fundamental studies have shown the enzyme subtilisin Carlsberg, which ordinarily hydrolyzes proteins, will carry out transesterification of N-acetyl-L-phenylalanine 2-chloro ethyl ester (NAPCE) with 1-propanol, when the reactants and enzyme are mixed in tetrahydrofuran containing a small amount of water (Affleck et al.). This research and work that has preceded it, gives a first indication of the potential of proteins, i.e. enzymes, as catalysts in organic synthesis.

The Polymerase Chain Reaction (PCR)

Another significant development in enzyme technology was the polymerase chain reaction (abbreviated PCR). Since about 1985, this method has significantly increased the ease and speed of DNA sequence isolation *in vitro*. PCR was developed by Cetus Corporation scientists in 1984 and 1985. It is an enzyme catalyzed reaction that facilitates gene isolation and avoids the complex process of cloning which requires the *in vivo* replication of a target DNA sequence integrated into a cloning vector in a host organism. PCR is initiated by DNA denaturation, followed by primer annealing, and then addition of a DNA polymerase and deoxynucleoside triphosphates to form a new DNA strand across the target sequence. This cycle, when repeated n times, produces 2^n times as much target sequence as was initially present. Thus 20 cycles of the PCR yields about a millionfold increase or amplification of the DNA. Applications include comparison of altered, uncloned genes to cloned genes, diagnosis of genetic diseases, and retrospective analysis of human tissue (Arnheim et al.). Methodology for using PCR to clone DNA has also been recently described, although unwanted mutagenesis poses limitations (Higuchi).

The PCR is an example of a biotechnology that touches other scientific disciplines (and even the movie industry). Consider the study of ancient DNA for tracking evolution. Several researchers have referred to this as molecular archeology, since preselected DNA, which has survived in ancient tissue for 45,000 years or more, can be sufficiently amplified to provide quantities that permit direct sequencing of the DNA. This approach, in effect, provides a time machine that enables students of molecular evolution "to retrieve and study ancient DNA molecules and thus to catch evolution red-handed" (Pääbo et al.).

Growth of Renewable Resources. There are already large industries, associated with corn processing and food manufacture that utilize enzymes and microbial fermentation on an extremely large scale. In these cases, production and substrate costs can be 70% of the total product costs, and cost efficient engineering becomes paramount. The development of the industry that produces fuel grade ethanol, used as a nonleaded octane booster and environmentally acceptable fuel oxygenate, had its roots in the development of high fructose corn syrup and the oil price shocks of 1973–1980 (see timeline in Table 1). Continuing growth is attributable to environmental regulations relating to clean air and transportation fuels, as well as a continued government subsidy. Future potential exists for production of consumer products in an environmentally acceptable manner from renewable and agricultural commodities. This includes plastics, paints, finishes, adsorbents and biomaterials. As the impact of biologically based production grows; so will the need for engineering. Bioprocess engineering, the discipline that deals with development, design, and operation of biologically based processes, will have a major role in the development of bioprocesses for transforming renewable resources into industrial chemicals.

Perhaps the ultimate application of biotechnology is to control ecological life support systems (or CELSS) for space travel. The concept of CELSS encompasses bioregenerative life support systems that would mimic earth's ecosystem, which recycles C, H, O and N, through a complex and interconnecting series of biological and biochemical transformations (Averner et al.). For long term space travel and habitation, food will need to be generated, and wastes recycled to support life (Westgate et al.). Such biological life support is needed if long term space travel, and particularly, colonization of Mars is to be attained. The technology that will result from development of CELSS also has direct application to understanding the earth's ecosystem, and addresses environmental issues. Bioremediation, the biological conversion of toxic wastes to nontoxic materials, could benefit from such research.

Technologies Needed to Reduce Costs. The future growth of renewable resources as a source of value-added biochemicals and oxygenated molecules will be driven by technologies rather than markets, as long as oil prices remain in the range of $15 to 20/barrel. There may be a few cases where a fermentation process or enzyme transformation could provide a specific product at an equivalent or lower cost compared to a chemical

process, while achieving a reduced environmental impact. In such a case, a biotechnology process might be used. An example is the production of fumaric acid for use as a food additive by fermentation, compared to fumaric acid by chemical synthesis for other purposes (Cao et al.). Some fermentation processes may offer attractive economics if there were a sustained increase in oil prices. Temporary spikes in oil prices could also offer windows of opportunity, although long term cost advantages would be needed to sustain growth of a renewable resource-based industry.

The attractiveness of renewable resources, aside from being renewable, lies in their ability to sequester and/or recycle CO_2, and their potential to be processed into useful products in an environmentally friendly manner. This has already been illustrated by corn. A renewable resource, it is used for food, animal feed, specialty starches, and as a source of sugars (mainly glucose) that can be fermented or converted to numerous value added products. See Fig. 6. Fats and oils derived from plants and animals/are examples of another type of renewable resource. These are the basis of industries that already produce a number of products that range from soaps to lubricants. See Fig. 7. The focus here is materials generated from sugars and polysaccharides. A thorough analysis of industrial uses of agricultural materials shows their potential (USDA). Current products range from fuel ethanol to starch adhesives, although the production of fuel alcohol from corn requires a government subsidy. Emerging technologies in ethanol production have decreased cost. The total energy required to process one gallon of ethanol with an energy value of 76,000 Btu/gallon was as high as 120,000 Btu when the industry started in 1977. Even when an energy credit of 32,000 Btu was assigned to the co-products of ethanol production (corn oil, gluten feed, gluten meal, and CO_2), there was still a net energy loss of 12,000. Research, and the rapid implementation of the resulting process improvements on an enormous scale by some of the ethanol producers, decreased energy costs. Process integration and implementation of new process technologies improved energy efficiency (USDA). (An example was a new anhydrous process at ADM for removing water from alcohol, which was installed in 1983). According to a stockholder's report, the company said that the process "will reduce total alcohol distillation energy by 35% or 4/gallon, and after shakedown is complete will probably be installed in all of our alcohol plants" (ADM). By 1993, the total energy requirement for an average-efficiency corn farm and an average-efficiency ethanol plant was 75,811 Btu/gal. With a co-product energy credit of 24,950 Btu, a net energy *gain* of Btu was achieved for modern, large-scale corn to ethanol routes. (Ryu and Lee, USDA).

Further improvements and decreased costs were anticipated due to better enzymes, bioreactor designs, and membranes for enhanced recovery of high-value co-products (Hohmann and Rendleman). Further significant reductions in cost, however, require lower feedstock prices. Thus, for example, the conversion of corn fiber, a cellulose containing co-product of ethanol production, to fermentable sugars could reduce costs by 3.0 to 7.5/gallon. (These cost comparisons were made relative to the cost of producing fermentation ethanol from corn in 1992, which was at $1.25/gallon, down from $1.35 to $1.45/gallon in 1980.) This is significant relative to the net feedstock (corn) costs of at least 44 per gallon. Cellulosic residues have the potential as being a less expensive substrate, but their composition and physical structure is different from starch. The cellulose structure is crystalline and resistant to being hydrolyzed. Consequently, a pretreatment is necessary to soften the cellulose prior to subjecting it to hydrolysis. Less expensive enzymes (that hydrolyze cellulose to glucose) are also needed to achieve a cost-effective hydrolysis step. Pentoses and hexoses occur in approximately 4:5 ratio, in cellulosic materials, compared to a 1:10 to 1:15 ratio in corn. Conversion of sugars from the pentosan and hexosan fractions of cellulosic materials will require microorganisms that ferment both pentoses and hexoses, to a single product (Hohmann and Rendleman).

Progress has been made in pretreatment (Weil et al., 1994a, Kohlmann et al., 1995a, Ladisch et al.) and enzyme hydrolysis (Weil et al., 1994b, Kohlmann et al. 1995b) as well as obtaining genetically engineered microorganisms that convert both pentoses and hexoses to ethanol (Lynd et al., Toon et al.). However, an economically viable process has not yet been achieved (Gulati et al.). Major improvements are still needed for all three technologies. Once these occur, their integration into existing ethanol plants is possible, as suggested by Figure 8. (Hohmann and Rendleman). The emergence of a cellulose-based industry would open the way for production of many other types of oxygenated chemicals and lead to the growth of a fermentation-based, renewable resources industry. However, this development is likely to be incremental, at first, and subject to government policies, much as was the case for other biotechnologies and in particular, HFCS. The plants which produce HFCS are also the major source of fermentation ethanol, large volumes of amino and carboxylic acids, and high-volume specialty products. These plants are well positioned to implement improvements in cellulose conversion, as another source of fermentable sugars, and then utilizing these sugars in an optimal manner for production of a diverse product mix. The future of the industry is likely to evolve from being based only on hexoses to an industry that utilizes and transforms both hexoses and pentoses to value-added products. Bioprocess engineering will play a major role in implementing technology for this transition, while the current and massive restructuring and consolidation of the high volume bioproducts sector will shape the business alliances needed for the evolution of a biobased industry.

Phytochemicals. Renewable resources are a source of natural plant chemicals. Chemicals derived from plant products are referred to as phytochemicals. These chemicals are formed as either primary or secondary metabolites. Balandrin et al. proposed that chemicals from primary metabolism could be classified as high volume-low value bulk chemicals with values less than $2/lb. Examples are vegetable oils, fatty acids (for making soaps or detergents), and carbohydrates (sucrose, starch, pectin or cellulose). Secondary metabolites are classified as high value with values ranging from $100/lb to $5000/gram. Examples are pyrethins and rotenone (used as pesticides); steroids and alkaloids such as *Digitalis* glycosides, anticancer alkaloids, and scopolamine. Secondary metabolites in plants often have an ecological role as pollination attractants or for mounting chemical defenses against microorganisms and insects. Secondary natural products often consist of complex structures with many chiral centers that are important to the biological activity of the materials. Plant derived proteins can also be classified as high value products. For example, papain is a proteolytic enzyme used as a meat tenderizer. Bromelain (from pineapple) has applications in milk clotting. Malt extract from barley has amylolytic enzymes used in beer brewing.

The summary of valuable products derived from plant materials by Balandrin et al., indicate that the recovery of bioactive compounds, classified as secondary metabolites, will continue to be an important source of medicines, pesticides, and specialty chemicals. The naturally occurring compounds could be numerous. These include: pesticides (pyrethrum from flowers, rotenone from roots, and nicotine); growth inhibitors of soil microorganisms (allelochemicals) plant growth regulators (brassinolide promotes growth at 1 gram per 5 acres); insect growth regulators; and medicinals (anti-cancer and analgesic drugs).

A recent example is given by the insecticidal properties of the neem tree (Stone). Neem seeds have chemicals that ward off more than 200 species of insects, while exhibiting less toxicity to humans than synthetic pesticides, and having little effect on predators of the insects. Neem seeds were valued at $300/ton in 1992. However, a lower price is needed if the extracts are to find widespread use as insecticides. The economic potential for naturally derived insecticides is large considering that about $\$2 \times 10^9$ of synthetic insecticides are sold annually in the U.S. (Stone).

Another class of plant-derived compounds are known as saponins. Saponins consists of a aglycone consisting of a titerpene, a steroid, or a steroidal alkaloid attached to a one or more sugar chains consisting of up to 11 monosaccharide units. One saponin derivative (*Abrusoside E*) is 150 times sweeter than sugar. Another group of saponins from *Yucca schidigera*, a medicinal plant used by Native North Americans, have antifungal activity and could be used as preservatives for processed foods. The plant itself is reported to be recognized by the FDA as safe for human use. A saponin from a member of the lily family, *Ornithogalum saundersiae*, has been found to exhibit little toxicity with respect to human cells, but is "remarkably toxic to malignant tumor cells" (Rouhi). Saponins from the South American tree, *Q. saponaria*, make animal vaccines more effective. Extracts from two types of African trees have been used to control Schistosomiasis, by eliminating host snails that harbor the disease (Rouchi).

Genetic engineering of bacteria or yeast to produce complex secondary metabolites remains a challenge, since these are formed via the joint action of many enzymes (i.e., many gene products). The culturing of plant cells, or plant tissues, to produce secondary metabolites could be used to produce some of the more valuable and bioactive compounds, and has been proposed for obtaining the chemotherapy agent, Taxol. It was estimated (in 1985) that a yield of 1 ggproduct/liter culture for compounds exceeding $1/gram in value is needed to obtain an economically viable process. Such

Processing starches and sugars into industrial and consumer products

Processing fats and oils into industrial and consumer products

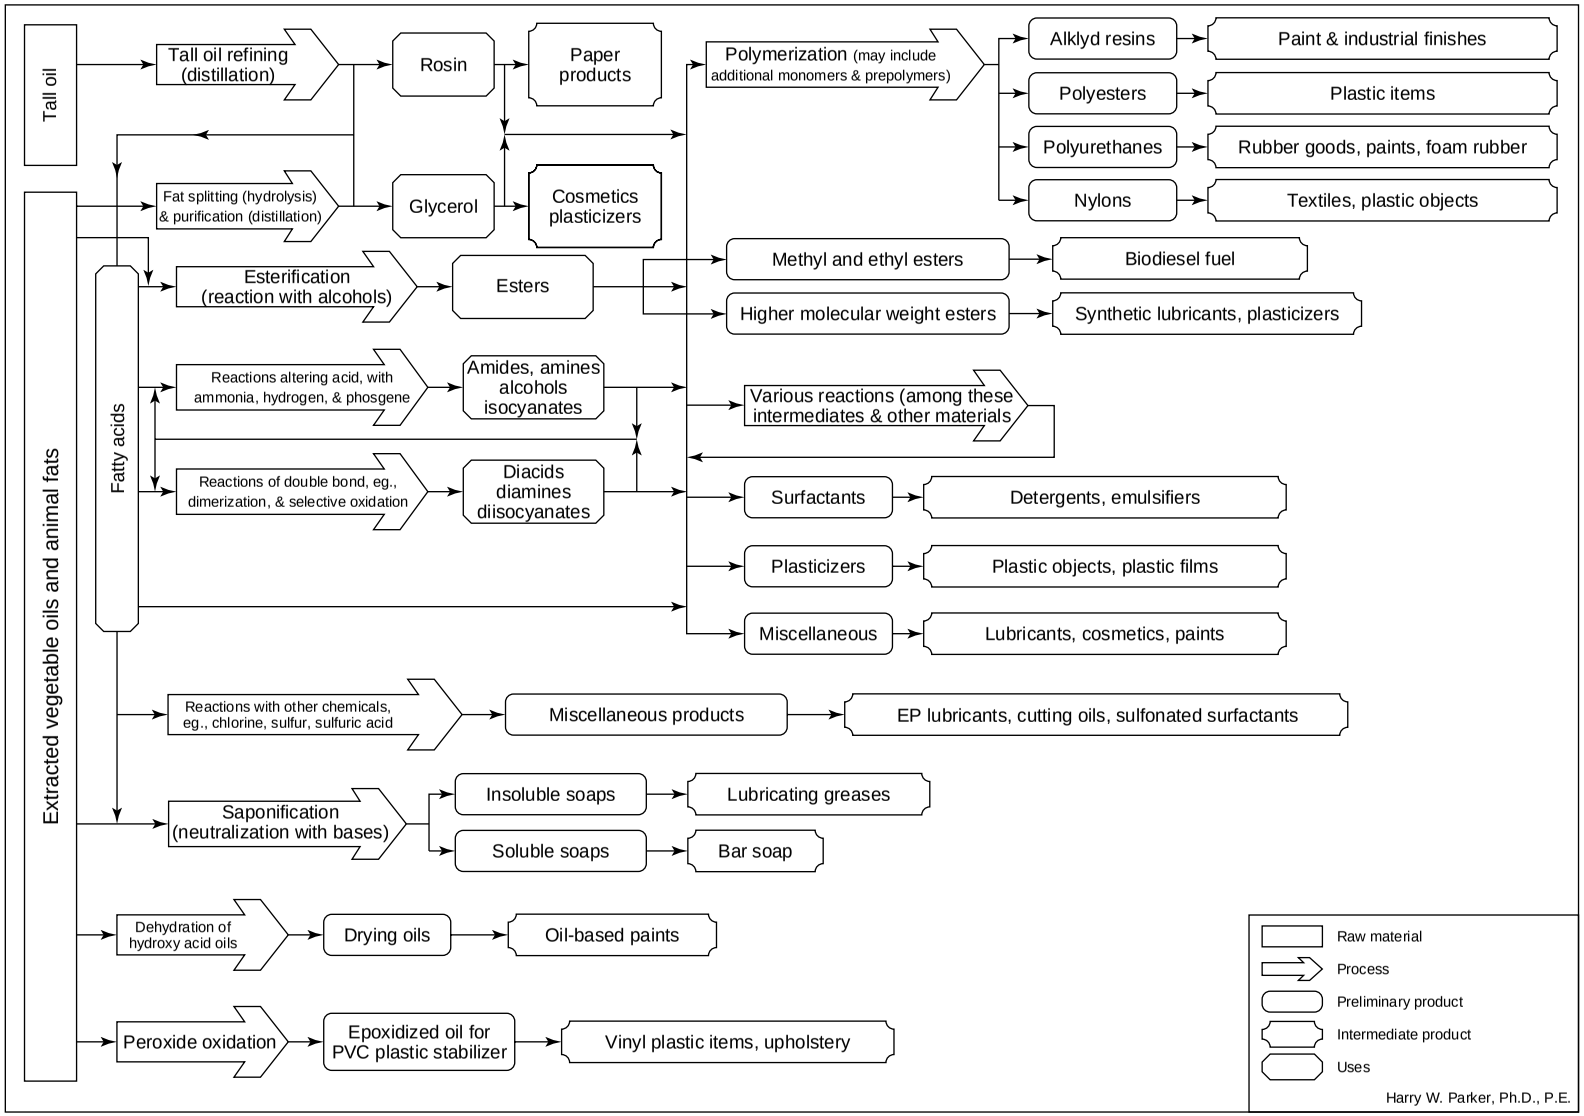

Fig. 7. Chart showing products derived from renewable sources of fats and oils. (*USDA*).

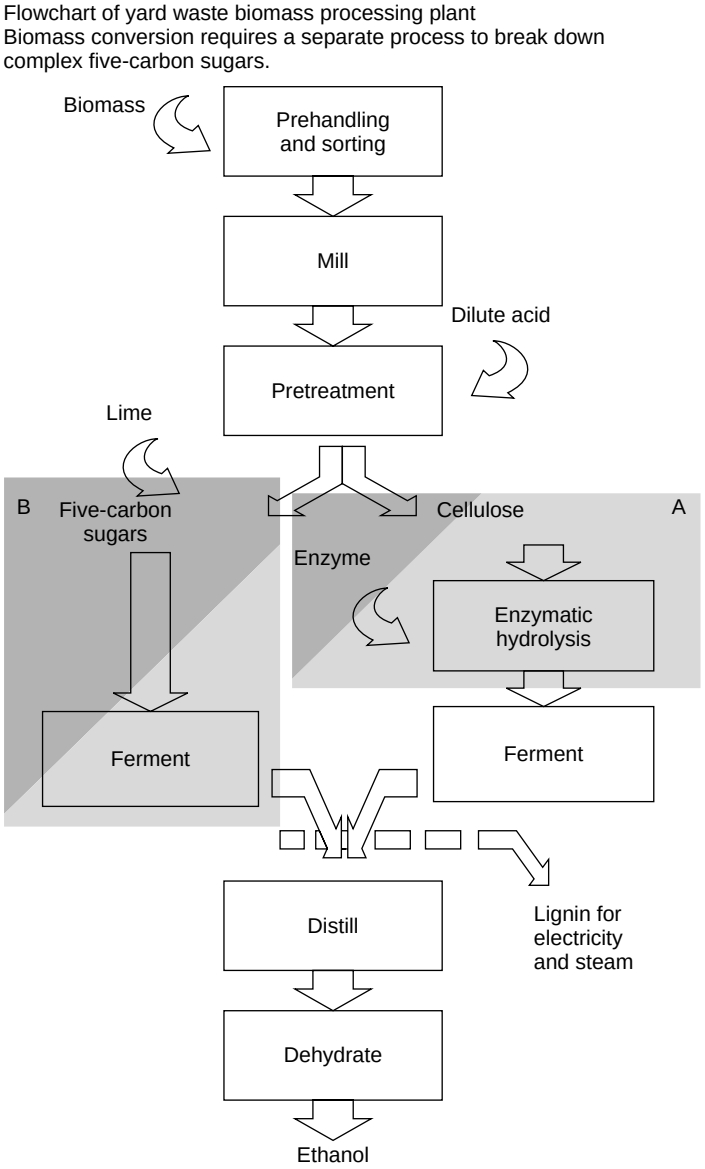

Fig. 8. Flow chart showing process for converting a cellulosic material (yard wastes i.e., grass clippings) to ethanol (from Hohmann and Rendleman).

an estimate may be optimistic. Even if successful, such cultures would still owe their start to the plants from which the compounds were identified, and the cells derived.

The advances in methods for genetic engineering of plants and propagating the transformed species could someday make use of the knowledge on the structure and function of plant metabolites. Attempts to determine plant genomes may soon be initiated. The combination of these factors could lead to development of other types of transgenic, pest resistant species, and perhaps the development of plant species grown to generate pharmaceuticals that are difficult or too costly to obtain by other means. These possibilities give a strong rationale for preserving the biodiversity of Earth's plant life, estimated between 250,000 and 750,000 species, since only 5 to 15% have been surveyed for biologically active compounds (Balandrin).

Bioseparations. Bioseparations are important to the extraction, recovery, and purification of plant derived products. The recovery and processing of plant derived molecules and the processing of renewable resources can be classified by the type of product. Primary metabolites are generally biopolymers. Natural rubber, condensed tannins and lignin, and high molecular weight polysaccharides, pectin, starch, cellulose, hemicellulose, and gums, are included in this category (Balandrin). Their processing into high-volume, relatively low-value products, are subject to economics of scale (bigger is better). The separation of the plant material into value-added components may require a combination of physical treatments combined with a change in the material's structure. For example, the processing of cellulose (in the cell walls of wood or agricultural residues) requires the cellulose be hydrolyzed to its monomer, glucose. This can only be readily achieved if the crystallinity of cellulose structure and its close association with lignin is disrupted and an enzyme or acid catalyst is used to depolymerize the cellulose polymer into its constituent monosaccharide. This processing, referred to as pretreatment/hydrolysis must be carried out in a very inexpensive manner, if it is to be practical. A commercially feasible process is yet to be demonstrated (Weil et al., 1994a, Kohlmann et al., 1995a, Ladisch et al.).

The recovery of secondary metabolites can be achieved by steam distillation, aqueous extraction, or extraction with an organic solvent. However, these bioproducts, whose molecular weights are below 2000, may be chemically unstable or only sparingly soluble in the extractant, thereby making their processing difficult. An example is given by annonaeous acetogenins from the Indiana banana (paw paw) tree (McLaughlin). These compounds have potential as chemotherapy agents against breast cancer, and are isolated from 100 samples of natural materials. These are chromatographed over a 25 cm $\times$ 2 m long silica gel column, in a gradient method that requires over a week to complete. The challenge is to increase the rate of preparative-scale chromatography so that samples, can be isolated and tested more quickly.

Impacts of Biotechnology on Drug Discovery and Biology

There are a number of disciplines that affect biotechnology. The fields of biology, molecular biology, biochemistry, chemistry, and biochemical engineering have made individual contributions to the rapid advance of biotechnology in a commercial sense. The demonstration that a gene from human pancreas cells could be introduced into a β-galactosidase operon, which in turn was introduced into *Escherichia coli*, so that the *E. coli* would produce human insulin, was a key event. The first steps in initiating this chain of events include the development of techniques for transgenosis, the artificial transfer of genetic information from bacterial cells to eucaryotic cells by transducing phages; isolation of a restriction enzyme that specifically cleaves certain parts of a small circular DNA known as a plasmid; the first cloning experiments in 1972 to 1973; electrophoresis and blotting techniques; and *in vitro* translation systems for converting mRNA into proteins (Old and Primrose, Alberts et al.). Other important enzymes were those that could ligate pieces of DNA (i.e., ligases), and would otherwise allow manipulation of DNA strands to obtain predetermined DNA sequences, i.e., genes, to be introduced into a bacterial plasmid.

The plasmid pBR322 was one of the most versatile artificial plasmid vectors since it contains ampicillin (Ap^R) and tetracycline (Tc^R) resistant genes, as well as desirable replication elements. These genes, when introduced into the cell, enable the bacteria to make enzymes that hydrolyze the two antibiotics. Hence, when a foreign gene is purposely engineered into the plasmid, and the plasmid is placed back into the bacterial host cell to obtain a transformed cell, the transformed cell will also be able to resist the two antibiotics as well as express a foreign protein corresponding to the gene. Transformed cells will grow in the presence of the antibiotic, while all other cells will be killed. Since transformations are not 100% efficient, the presence of ampicillin and tetracycline resistant genes in a recombined plasmid enable the researcher to select for the transformed cells by growing them in a medium that contains the antibiotics.

The pBR322 plasmid is 4362 base pairs long, and is completely sequenced (Old and Primrose). Plasmid pBR322 was the starting point for constructing the plasmid pSomII-3 containing a chemically synthesized gene for the small hormone, somatostatin (Itakura et al.). These developments resulted in a new language, as well as a new technology. Consequently, bioprocess engineers involved in reducing recombinant technology to commercial practice now must learn a new vocabulary to communicate with bioscientists.

At a meeting convened by Eli Lilly and Co. in Indianapolis, in 1976, these tools, together with a method for producing copious quantities of mRNA for insulin by a special tumor cell known as an insulinoma apparently helped to encourage a race for the cloning of the human insulin gene into *E. coli*. The ensuing three years of intense activity (about 1976 to 1979) make up the fascinating story told by Hall.

The realization that there is an interface where biology, fermentation, and recovery technologies all affect each other (Swartz), gave rise to new challenges. Questions that may arise as a process is designed, scale-up, and operated are if recovery is difficult, can the protein be modified to

make it easier to purify? If protein refolding gives low yields, can the molecular biologist clone the gene to obtain a proactive form? If test tube scale production gives low yields, can the biochemical engineer optimize conditions to give a better yield? If the product is intracellular, how can the cell best be programmed to respond to a step input to the fermentation, to turn on protein production machinery? How can a separation system be modified to handle complex mixtures containing low titers of the final product? Another important question in a practical context: How much will this cost and how long will it take?

The response to these types of questions has fostered evolution of a team or cross-disciplinary approach to problem solving in the biotechnology industry.

Biotechnology and Biological Research. Genetic engineering techniques have facilitated studies of proteins in plant and animal cells, which otherwise would not have been possible since these proteins (such as DNA polymerases, reverse transcriptase, and ribozymes) are normally present in very small amounts. Their study led, in turn, to their use as tools in further understanding cellular function and genetics, as well as practical applications such as PCR (requires polymerase) and development of antiviral drugs (a possible application of ribozymes) (Pääbo et al., Gibbons). Genetic engineering techniques have been used to amplify mammalian proteins in bacterial systems, so that sufficient protein becomes available for classical study using established enzymology techniques. Some examples are neural peptides, which impact hypertension, and co-reductases implicated in heart disease.

Drug Discovery. Drug discovery was thought to be the area that would benefit enormously from techniques developed through genetic engineering. Proteins having possible therapeutic value are often difficult to study because their *in vivo* concentration in mammalian systems is very low, or because they are difficult to isolate due to limited specimen availability. Once a gene can be identified, molecular biology techniques can be used to produce larger quantities of the protein, thus facilitating its study. The interleukins are an example of this approach, where it is estimated that more interleukin was produced during several years of its discovery phase than was generated since the beginning of humanity. These cytokines are now being examined or used in treatment of wound healing, cancer, and immune deficiencies (Thayer, 1991).

Site specific mutations can also be achieved using recombinant techniques. This facilitates study of a protein's activity if given amino acids are replaced in its structure. Thus, the protein's binding properties with respect to inhibitors, where the inhibitors represent an experimental drug, can be studied.

Biotechnology for Value Added Products from Renewable and Nonrenewable Resources. Biotechnology is usually identified with the microbial production of pharmaceuticals (including vitamins, hormones, alkaloids, antitumor drugs, and interferon). The proliferation of applied molecular biology to microbial, animal, and plant cell modifications, together with a heightened awareness by the chemical industry of the potential of biotechnology is adding a new dimension. Genetic modification techniques are resulting in new types of plant systems that hold the promise of increased productivity and enhanced disease and pest tolerance in the context of integrated agricultural and land management techniques. This is changing the types of agricultural chemicals needed, and hence, is affecting an important sector of the chemical industry. Engineering expertise is needed to translate research advances of biochemists, microbiologists, and agricultural scientists to commercial scale practice.

Agriculture will be an essential component of the emerging biotechnology industry, both as an end-user of technological advances and supplier of the carbohydrates and other biological materials that will be needed as feed stocks by a rapidly growing industry. Development of crops, with enhanced levels of natural pesticides, are beginning to reduce the need for chemical pesticides. Such crops are already undergoing trials.

Bioprocess Engineering and Economics

Evaluation of the engineering economics of bioprocesses is becoming increasingly important as new products move from the research and development phase into commercial production and test marketing. Products of current interest include biological molecules for human or animal health, monoclonal antibodies for diagnostic purposes, enzymes, biochemical intermediates, antibiotics and amino acids. Engineers and scientists sometimes need to obtain a first estimate of relative costs to choose process alternatives and establish magnitude or order product costs. Since there is such a broad range of products with different economic criteria, a single type of cost calculation approach cannot be used for all these cases. Consequently, there appears to be a need for procedures for estimating the relative economics for each type of product on an internally consistent basis. This article addresses the basic concepts of a thought process which Taylor calls "economic decision making."

Bioprocess economics require the engineer or scientist to be able to quickly recognize limiting technical parameters that are likely to be encountered upon scale-up. Processing schemes that minimize operational difficulties and costs must be selected accordingly. Hence, process conceptualization is an important part of the evaluation process and must reflect regulatory constraints as well as transport and kinetic phenomena required to size key pieces of equipment. Examples are oxygen transfer, mixing, and heat removal in a fermentation (i.e., compression and heat exchange costs); maintaining sterile conditions in a continuous bioreactor (productivity and regulatory issues); or predicting resolution in a chromatography column (separation costs). In some cases it is difficult to carry out calculations since physical properties (for example, broth viscosities and heat capacities, or diffusion coefficients of biomolecules) are not well defined during the early stages of a research and development program. Hence, approaches and heuristic rules that might be used in this situation are also needed.

Disparate elements, which affect economic decisions for bioprocesses, can be combined into a logical approach. An attempt must be made to combine fundamentals of bioreactor design, downstream processing, and properties of biomolecules in the context of process evaluation. The ability to set technical priorities based on economic assessment is essential, and requires communication between researchers, process engineers, technical managers, and marketing managers.

Bioseparations and Bioprocess Engineering

The large scale purification of proteins and other bioproducts is the final production step, prior to product packaging, in the manufacture of therapeutic proteins, specialty enzymes, diagnostic products and value added products from agriculture. These biochemical separation steps purify biological molecules or compounds obtained from biological sources and hence are referred to as bioseparations. The essence of large-scale bioseparations is both art and science. Bioseparations often evolve from laboratory scale techniques. These are adapted and scaled-up to satisfy the need for larger amounts of extremely pure, test quantities of the product for analysis, characterization, testing of efficacy, clinical or field trials, and finally, full scale commercialization. The uncompromising standards for product quality, driven by commercial competition, end-use applications, and regulatory oversight, provide many challenges to the scale-up of protein purification and biochemical separations. The rigorous quality control of manufacturing practices and the complexity and liability of the macromolecules being processed provide other practical issues, which must be addressed.

The emphasis of research and development in bioseparations is currently on the purification of proteins derived from recombinant fermentations and cell culture. This is to be expected since the purification of proteins and other bioproducts is a critical and expensive part of most biotechnology based manufacturing processes, and may account for 50% or more of production costs (NAS). While overall production costs have been considered to be secondary to being the first to market, this perspective is changing as the price, and value, of new bioproducts is decreasing. When the volume of the products is small and the price is high (Table 6), being the first to market, together with attaining high product quality (in terms of purity, activity, dependability, or flexibility) are the major competitive advantages (NAS, Wheelwright, Bisbee). Although the data in Table 6 will change with time as prices change, the extraordinarily high values illustrate the difference between these protein biopharmaceuticals and other drugs, or larger volume bioproducts.

Bioseparations are important in assuring product quality, but manufacturing cost is likely to be secondary for these types of products. When the scale of production of new bioproducts increases from kilograms to tons, the need for cost-effective purification schemes is also increased in importance. High volume products could range from serum (blood) proteins produced by recombinant organisms, to organic acids, enzymes, and food additives obtained from large scale fermentations or from enzyme transformations.

A major technical challenge in the production of biopharmaceuticals is the "development of high-resolution protein purification technologies that

TABLE 6. UNIT VALUES AND RELATIVE PRODUCTION QUANTITIES FOR SELECTED APPROVED BIOPHARMACEUTICALS

Product	Year Approved	Approximate Selling Price $/g	Amount of Product for $200 million in Sales, kg
Human Insulin	1982	375[b]	530.
Tissue Plasminogen Activator	1987	23,000	8.7
Growth Hormone	1985	35,000	5.7
Erythropoetein (Epogen)	1989	840,000	0.24
GM CSF	1991	384,000	0.52
G-CSF	1991	450,000	0.44

[a] Adapted from Table 2–1, National Academy of Sciences, 1992 (NAS) and data of Bisbee.
[b] A 1996 estimate places the selling price at $130/g, thus indicating a significant decrease in price (Petrides).

are relatively inexpensive, are easily scaled-up and have minimal waste-disposal requirements (NAS)." Separation processes for bioprocessing of renewable resources and agricultural products will benefit from development of "more efficient separations for recovering fermentation products, sugars, and dissolved materials from water," and in particular, lowering the cost of separating water from the product in the fermentation broth (NAS). The bioprocess engineer must therefore be familiar with principles of a wide range of bioseparations techniques, and the practice of the dominant methods likely to be used in the industry.

The most popular method for purifying protein biopharmaceuticals is some form of liquid chromatography due to its resolving powers. Large-scale liquid chromatography can also be used to purify high volume bioproducts including sugars, antibiotics, vitamins, nucleosides, organic acids, and alcohols. However, chromatography is only one of the many steps needed to purify bioproducts. Recovery and purification steps preceding chromatography may include centrifugation or filtration in order to remove solids; membrane filtration or fractionation to separate large molecules from small ones; and precipitation, crystallization, extraction, and/or adsorption to concentrate the product.

It is difficult to predict which combinations of separation methods might be used to purify a new product on the process scale. It is hoped that the combination of principles, practice, and a sense of economics that drive the industry, will assist process engineers and scientists in selecting time-efficient and cost-effective purification methods.

The engineering of separation processes for biotechnology products, also requires a fundamental understanding of the biological materials being processed. The range of products derived from genetically modified organisms will have a diverse range of properties, but a common requirement that they be recovered, concentrated, and purified to give a safe and, in many cases, biologically active product. Bioseparations engineering combines the disciplines of engineering, life sciences, chemistry, and medicine in order to match the unique properties of biomolecules with the most appropriate techniques for their large scale purification. The rapid development of new methods, organisms, and molecules means that these products will be continually changing, as will the methods by which they are purified. Consequently, the design of bioseparation processes requires that the engineering principles of individual separation steps be understood, so that they can be combined into sequences of steps that result in the needed product purity at a cost which is clearly defined and calculated.

Parts of this section taken directly, or paraphrased from Ladisch, which was presented as a plenary lecture in the Separations Technology Program of the 1997 Annual meeting of the American Institute of Chemical Engineers.

BIOPSY. Removal and microscopic examination of a portion of living tissue, to establish a diagnosis.

BIOREMEDIATION. Bioremediation is the process of judiciously exploiting biological processes to minimize an unwanted environmental impact; usually it is the removal of a contaminant from the biosphere.

Bioremediation is already a commercially viable technology. There are significant opportunities to enlarge upon this success. Bioremediation has applications in the gas phase, in water, and in soils and sediments. For water and soils, the process can be carried out *in situ*, or after the contaminated medium has been moved to some sort of contained reactor (*ex situ*). The former is generally rather cheaper, but the latter may result in such a significant increase in rate that the additional cost of manipulating the contaminated material is overshadowed by the time saved. Bioremediation may explicitly exploit bacteria, fungi, algae, or higher plants. Each, in turn, may be part of a complex food-web, and optimizing the local ecosystem may be as important as focusing solely on the primary degraders or accumulators.

Bioremediation usually competes with alternative approaches to achieving an environmental goal. It is typically among the least expensive options, but an additional important consideration is that in many cases bioremediation is a permanent solution to the contamination problem, since the contaminant is completely destroyed or collected. Some of the alternatives technologies, such as thermal desorption and destruction of organics, are also permanent, solutions, but the simplest, removing the contaminant to a dump site, merely moves the problem, and may well not eliminate the potential liability. Furthermore, by its very nature bioremediation addresses the bioavailable part of any contamination. The same cannot necessarily be said for nonbiological technologies, which may leave bioavailable contaminants at low levels.

Bioremediation also has the advantage that it can be relatively nonintrusive, and can sometimes be used in situations where other approaches would be severely disruptive. On the other hand, bioremediation is usually slower than most physical techniques, and may not always be able to meet some very strict cleanup standards. Nevertheless, it is becoming a widely used technology.

Organic Contaminants

Hydrocarbons. Hydrocarbons get into the environment from biogenic and fossil sources. Methane is produced by anaerobic bacteria in enormous quantities in soils, sediments, ruminants and termites, and it is consumed by methanotrophic bacteria on a similar scale. Submarine methane seeps support substantial oases of marine life, with a variety of invertebrates possessing symbiotic methanotrophic bacteria. Thus, methanotrophic bacteria are ubiquitous in aerobic environments. Plants generate large amounts of volatile hydrocarbons, including isoprene and a range of terpenes. These compounds provide an abundant substrate for hydrocarbon-degrading organisms.

Crude oil has been part of the biosphere for millennia, leaking from oil seeps on land and in the sea. Crude oils are very complex mixtures, primarily of hydrocarbons although some components do have heteroatoms such as nitrogen (e.g., carbazole) or sulfur (e.g., dibenzothiophene). Chemically, the principal components of crude oils and refined products can be classified as aliphatics, aromatics, naphthenics, and asphaltic molecules. When crude oils reach the surface environment the lighter molecules evaporate, and are either destroyed by atmospheric photooxidation or are washed out of the atmosphere in rain, and are biodegraded. Some molecules, such as the smaller aromatics (benzene, toluene, etc.) have significant solubilities, and can be washed out of floating slicks, whether these are at sea, or on terrestrial water tables. Fortunately the majority of molecules in crude oils, and refined products made from them, are biodegradable, at least under aerobic conditions.

Biodegradation. Methane and the volatile plant terpenes are fully biodegradable by aerobic organisms, and most refined petroleum products are essentially completely biodegradable under aerobic conditions. The least biodegradable material, principally polar molecules and asphaltenes, lacks the "oily" feel and properties that are associated with oil. These are essentially impossible to distinguish from more recent organic material in soils and sediments, such as the humic and fulvic acids, and appear to be biologically inert.

Numerous bacterial and fungal genera have species able to degrade hydrocarbons aerobically and the pathways of degradation of representative aliphatic, naphthenic and aromatic molecules have been well characterized in at least some species. It is a truism that the hallmark of an oil-degrading organism is its ability to insert oxygen atoms into the hydrocarbon, and there are many ways in which this is achieved.

In recent years it has become clear that at least some hydrocarbons are oxidized by bacteria under completely anaerobic conditions, where the oxygen is probably coming from water. Limited hydrocarbon biodegradation has now been shown under sulfate-, nitrate-, carbon dioxide- and ferric iron-reducing conditions (Table 1). It is noteworthy that while organisms capable of aerobic oil biodegradation seem to be ubiquitous, organisms capable of the anaerobic degradation of hydrocarbon have to date only been found in a few places.

Although the majority of molecules in crude oils and refined products are hydrocarbons, the U.S. Clean Air Act amendment of 1990 mandated the addition of oxygenated compounds to gasoline in many parts of the United States. The requirement is usually that 2% (w/w) of the fuel be oxygen, which requires that 5–15% (v/v) of the gasoline be an oxygenated additive (e.g., methanol, ethanol, methyl *tert*-butyl ether (MTBE), etc.). Although methanol and ethanol are readily degraded under aerobic conditions, the degradability of MTBE remains something of an open question. The

TABLE 1. HYDROCARBONS THAT HAVE BEEN SHOWN TO BE BIODEGRADED UNDER ANAEROBIC CONDITIONS

Electron acceptor	Substrate
Nitrate (to nitrogen)	Heptadecene
	toluene, ethylbenzene, xylene
	naphthalene
	terpenes
Iron(III) (to iron(II))	Toluene
Manganese(IV) (to Mn(II))	Toluene
Sulfate (to sulfide)	Hexadecane, alkylbenzenes
	benzene
	naphthalene, phenanthrene
CO_2 (to methane)	Toluene, xylene

compound was previously very rare in the environment, but now it is one of the major chemicals in commerce. At first it seemed that the compound was completely resistant to biodegradation, but complete mineralization has now been reported. Whether biodegradation can be optimized for effective bioremediation remains to be seen.

Bioremediation. Crude oil and refined products are readily biodegradable under aerobic conditions, but they are only incomplete foods since they lack any significant nitrogen, phosphorus, and essential trace elements. Bioremediation strategies for removing large quantities of hydrocarbon must therefore include the addition of fertilizers to provide these elements in a bioavailable form.

Air. Hydrocarbon vapors in air are readily treated with biofilters. These are typically rather large devices with a very large surface area provided by bulky material such as a bark or straw compost. The contaminated air, perhaps from a soil vapor-extraction treatment, or from a factory using hydrocarbon solvents, is blown through the filter, and organisms, usually indigenous to the filter material or provided by a soil or commercial inoculum, grow and consume the hydrocarbons.

Sea. Significantly more oil reaches the world's oceans from municipal sewers than widely covered crude oil spills. Physical collection of spilled oil is the preferred remediation option, but if skimming is unable to collect the oil, biodegradation and perhaps combustion or photooxidation are the only routes for eliminating of the spill. One approach to stimulating biodegradation is to disperse the oil with chemical dispersants. Modern dispersants and application protocols stimulate biodegradation by increasing the surface area of the oil available for microbial attachment, and perhaps providing nutrients to stimulate microbial growth.

Shorelines. The successful bioremediation of shorelines affected by the spill from the *Exxon Valdez* in Prince William Sound, Alaska, was perhaps the largest project to date. Bioremediation focused on the addition of nitrogen and phosphorus fertilizers to partially remove the nutrient-limitation on oil degradation. Of course the addition of fertilizers was complicated by the fact that oiled shorelines were washed by tides twice a day. Two fertilizers were used in the full-scale applications; one, an oleophilic product known as Inipol EAP22 (trademark of CECA, Paris, France), was a microemulsion of a concentrated solution of urea in an oil phase of oleic acid and trilaurethphosphate, with butoxyethanol as a cosolvent. This product was designed to adhere to oil, and to release its nutrients to bacteria growing at the oil-water interface. The other fertilizer was a slow-release formulation of inorganic nutrients, primarily ammonium nitrate and ammonium phosphate, in a polymerized vegetable oil skin. This product, known as Customblen (trademark of Grace-Sierra, Milpitas, California), released nutrients with every tide, and these were distributed throughout the oiled zone as the tide fell. Fertilizer application rates were carefully monitored so that the nutrients would cause no harm, and the rate of oil biodegradation was stimulated between two- and five-fold.

Areas where there are currently few remediation options but where bioremediation may provide an option include oiled marshes, mangroves, and coral reefs. Bioremediation also offers options for dealing with oiled material, such as seaweed, that gets stranded on shorelines; composting has been shown to be effective.

Groundwater. Spills of refined petroleum product on land, and leaking underground storage tanks, sometimes contaminate groundwater. Standalone bioremediation is an option for these situations, but "pump and treat" is the more usual treatment. Contaminated water is brought to the surface, free product is removed by flotation, and the cleaned water reinjected into the aquifer or discarded. Adding a bioremediation component to the treatment, typically by adding oxygen and low levels of nutrients, is an appealing and cost-effective way of stimulating the degradation of the residual hydrocarbon not extracted by the pumping. This approach is becoming widely used.

Typically only small aromatic molecules, the infamous BTEX (benzene, toluene, ethylbenzene, and xylenes), are soluble enough to contaminate groundwater. With the advent of oxygenated gasolines, it is expected that these oxygenates [ethanol, methanol, MTBE (methyl-*tert*-butyl ether) etc] will also be found in groundwater. These contaminants are biodegradable, and some biodegradation is probably already occurring when the contamination is discovered. The cheapest approach to remediation is, thus, to allow this intrinsic process to continue.

Intrinsic bioremediation is becoming an acceptable option in locations where the contaminated groundwater poses little threat to environmental health. Nevertheless, it may not be the lowest cost option if there are extensive monitoring and documentation costs involved for several years. In such cases it may well be more cost effective to optimize conditions for biodegradation.

One approach is to optimize the levels of electron acceptors. Slow release formulations of inorganic peroxides, such as magnesium peroxide, have recently been used with success. Nitrate may be added, although there are sometimes regulatory limitations on the amount of this material that may be added to groundwater. Ferric iron availability may be manipulated by adding ligands.

If there are significant amounts of both volatile and nonvolatile contaminants, remediation may be achieved by a combination of liquid and vapor extraction of the former, and bioremediation of the latter. This combination has been termed "bioslurping".

The majority of remediation operations include stopping the source of the contamination, but in some cases this is impossible, either because of the location of the spill, or because it is over a large area, and not a point source. In these situations it may be possible to intercept the flow of contaminated groundwater on-site, and ensure that no contamination passes. Approaches include biowall, trench biosparge, funnel and gate, bubble curtain, sparge curtain and engineered trenches and gates. Both aerobic and anaerobic designs have been successfully installed.

Where there are large volumes of contaminated water under a small site, it is sometimes most convenient to treat the contaminant in a biological reactor at the surface.

Of course the presence of a liquid phase of hydrocarbon in a soil gives rise to vapor contamination in the vadose zone above the water table. This can be treated by vacuum extraction, and the passage of the exhaust gases through a biofilter (see above) can be a cheap and effective way of destroying the contaminant permanently.

Soil. Spills from production facilities and pipelines often involve both oil and brine. Successful bioremediation strategies must therefore include remediating the brine. In wet regions the salt is eventually diluted by rainfall, but in arid regions, and to speed the process in wetter regions, gypsum is often added to restore soil porosity.

Many hydrocarbons bind quite tightly to soil components, and are thereby less available to microbial degradation. Intrinsic biodegradation occurs, but it usually only removes the lightest refined products, such as gasoline, diesel and jet fuel. Active intervention is typically required. Usually the least expensive approach is *in situ* remediation, typically with the addition of nutrients, and the attempted optimization of moisture and oxygen by tilling.

Deeper contamination may be remedied with bioventing, where air is injected through some wells, and extracted through others to both strip volatiles and provide oxygen to indigenous organisms. Fertilizer nutrients may also be added. This is usually only a viable option with lighter refined products.

A recent suggestion has been to use plants to stimulate the microbial degradation of the hydrocarbon (hydrocarbon phytoremediation). The plants are proposed to help deliver air to the soil microbes, and to stimulate microbial growth in the rhizosphere by the release of nutrients from the roots. The esthetic appeal of an active phytoremediation project can be very great.

When soil contamination extends to some depth it may be preferable to excavate the contaminated soil and put it into "biopiles" where oxygen, nutrient and moisture levels are more easily controlled. Composting by the

addition of readily degradable bulking agents is also a useful option for relatively small volumes of excavated contaminated soil.

Slurry bioreactors offer the most aggressive approach to maximizing contact between the contaminated soil and the degrading organisms. Slurry bioreactors are usually the most expensive bioremediation option because of the large power requirements, but under some conditions this cost is offset by the rapid biodegradation that can occur.

In all these cases it is important to bear in mind that although the majority of hydrocarbons are readily biodegraded, some are very resistant to microbial attack. It is thus important to run laboratory studies to ensure that the contaminant is sufficiently biodegradable that clean-up targets can be met.

Halogenated Organic Solvents

Constituents. Halogenated organic solvents are widely used in metal processing, electronics, dry cleaning and paint, paper and textile manufacturing and are fairly widespread contaminants. Unlike the hydrocarbons, which usually float on water, the halogenated solvents typically have specific gravities greater than 1, and they generally sink to the bottom of any groundwater, and float on the bedrock. For this reason they are sometimes known as DNAPLs for dense nonaqueous phase liquids.

Biodegradation. Halogenated solvents are degraded under aerobic and anaerobic conditions. The anaerobic process is typically a reductive dechlorination that progressively removes one halide at a time.

The simplest chlorinated alkanes, alkenes, and alcohols (e.g., chloromethane, dichloromethane, chloroethane, 1,2-dichloroethane, vinyl chloride, and 2-chloroethanol) serve as substrates for aerobic growth for some bacteria, but the majority of halogenated solvents cannot support growth. Nevertheless these compounds are mineralized under aerobic conditions.

Bioremediation

Air. Biofilters are an effective way of dealing with air from industrial processes that use halogenated solvents such chloromethane, dichloromethane, chloroethane, 1,2-dichloroethane and vinyl chloride, which support aerobic growth. Both compost-based dry systems and trickling filter wet systems are in use. Similar filters could be incorporated into pump-and-treat operations.

Groundwater and Soil. Halogenated solvents have contaminated soils and groundwater throughout the industrialized world, and remediation has a high priority. Since the solvents are so dense, they are typically found on the bedrock underlying aquifers. Pumping out the liquid phase is an obvious first step if the contaminant is likely to be mobile, but *in situ* bioremediation is a promising option. Thus, the U.S. Department of Energy is investigating the use of anaerobic *in situ* degradation of carbon tetrachloride with nitrate as electron acceptor, and acetate as electron donor.

Trichloroethylene, the most frequent target of remediation, is only metabolized co-metabolically. Remediation operations thus incorporate the addition of co-metabolized substrate.

Plants may have a role to play in enhancing microbial biodegradation of halogenated solvents, for it has recently been shown that mineralization of radiolabelled trichlorothylene is substantially greater in vegetated rather than unvegetated soils, indicating that the rhizosphere provides a favorable environment for microbial degradation of organic compounds.

Methane has been used in aerobic bioreactors that are part of a pump-and-treat operation, and toluene and phenol have been used as co-substrates at the pilot scale. Anaerobic reactors have also been developed for treating trichloroethylene.

Groundwater contaminated with other halogenated solvents can also be treated in aboveground reactors. Aerobic reactors are useful for those compounds that can support growth. Sequential anaerobic and aerobic reactors are capable of mineralizing tetrachloroethylene.

Halogenated Organic Compounds

Constituents. Complex halogenated organic compounds have been widely used in commerce in the last fifty years. Representative examples are pentachlorophenol, (2,4-dichlorophenoxy)acetate, DDT and polychlorinated biphenyls (PCBs). They may not seem a good target for bioremediation but some successful applications have been developed.

Biodegradation. An important characteristic of degradation is the cleavage of carbon–chlorine bonds, and the enzymes that catalyze these reactions, the dehalogenases, are being characterized. The reductive dechlorination seen with carbon tetrachloride and tetrachloroethylene seems to be a general phenomenon, and even compounds as persistent as DDT and the polychlorinated biphenyls are reductively dechlorinated under some conditions, particularly under methanogenic conditions. Some compounds, such as pentachlorophenol, can be completely mineralized under anaerobic conditions, but the more recalcitrant ones require aerobic degradation after reductive dehalogenation.

Bioremediation

Soil. Pentachlorophenol has been the target of bioremediation at a number of wood-treatment facilities, and good success has been achieved in several applications. It is rarely the sole contaminant, and is often present with polynuclear hydrocarbons from coal creosote. *In situ* degradation has been stimulated by bioventing, where air is injected through some wells, and extracted through others to both strip volatiles and provide oxygen to indigenous organisms. Just as with the halogenated solvents, it seems that plants stimulate microbial degradation of pentachlorophenol in the rhizosphere.

The kinetics of such *in situ* degradation are rather slow, however, and more active bioremediation is usually attempted.

A major concern when remediating wood-treatment sites is that pentachlorophenol was often used in combination with metal salts, and these compounds, such as chromated-copper-arsenate, are potent inhibitors of at least some pentachlorophenol degrading organisms. Sites with significant levels of such inorganics may not be suitable candidates for bioremediation.

The phenoxy-herbicide, 2,4-D, has been successfully bioremediated in a soil contaminated with such a high level of the compound (710 ppm) that it was toxic to microorganisms. Success relied on washing a significant fraction of the contaminant off the soil and adding bacteria enriched from a less contaminated site. Success was achieved in remediating both soil washwater and soil in a bioslurry reactor. 2,4-D is also effectively degraded in composting, with about half being completely mineralized, and the other half becoming incorporated in a nonextractable form in the residual soil organic matter.

The bioremediation of polychlorinated biphenyls in soils in receiving significant attention because these compounds are quite widely distributed in the environment, either from leaking electrical transformers or sometimes because they were applied as part of road maintenance. In the latter case, the contamination usually includes petroleum hydrocarbons, and unfortunately it seems that the two contaminants inhibit the degradation of each other. Nevertheless, cultures are being found that can degrade both polychlorinated biphenyls and petroleum hydrocarbons. There is also interest in the role of rhizosphere organisms in polychlorinated biphenyl degradation, particularly since some plants exude phenolic compounds into the rhizosphere that can stimulate the aerobic degradation of the less chlorinated biphenyls.

Groundwater. A successful groundwater bioremediation of pentachlorophenol is being carried out at the Libby Superfund site described above. A shallow aquifer is present at 5.5 to 21 m below the surface, and a contaminant plume is nearly 1.6 km in length. Nutrients and hydrogen peroxide were added at the source area and approximately half way along the plume, and pentachlorophenol concentrations decreased from 420 ppm to 3 ppm where oxygen concentrations were successfully raised.

Pentachlorophenol is readily degraded in biofilm reactors, so bioremediation is a promising option for the treatment of contaminated groundwater brought to the surface as part of a pump-and-treat operation.

River and Pond Sediments. Much of the work on polychlorinated biphenyls has focused on the remediation of aquatic sediments, particularly from rivers, estuaries, and ponds. Harkness and co-workers have successfully stimulated aerobic biodegradation in large caissons in the Hudson River by adding inorganic nutrients, biphenyl, and hydrogen peroxide, but found that repeated addition of a polychlorinated-biphenyl degrading bacterium (*Alcaligenes eutrophus* H850) had no beneficial effect. Whether this approach can be scaled-up for large-scale use, with a net environmental benefit, remains to be seen.

Nonchlorinated Pesticides and Herbicides

Constituents. It is unusual for these compounds to become contaminants where they are applied correctly, but manufacturing facilities, storage depots and rural airfields where crop-dusters are based have had spills that can lead to long lasting contamination.

Biodegradation. The vast majority of pesticides, herbicides, fungicides, and insecticides in use today are biodegradable, although the intrinsic biodegradability of individual compounds is one of the variables used in deciding which compound to use for which task. Some herbicides are acutely toxic to plants that absorb them, but are so readily degraded in soil

that seeds can be planted at the same time as the herbicide application. Other herbicides are known to be effective at preventing plant growth for many months, and are used in situations where this is the desired goal.

Compounds with organophosphate moieties, such as Diazinon, Methyl Parathion, Coumaphos and Glyphosate are usually hydrolyzed at the phosphorus atom. Indeed several *Flavobacterium* isolates are able to grow using parathion and diazinon as sole sources of carbon.

Very few pure cultures of microorganisms are able to degrade triazines such as Atrazine, although some *Pseudomonads* are able to use the compound as sole source of nitrogen in the presence of citrate or other simple carbon substrates. The initial reactions seem to be the removal of the ethyl or isopropyl substituents on the ring, followed by complete mineralization of the triazine ring.

Nitroaromatic compounds, such as Dinoseb, are degraded under aerobic and anaerobic conditions. The nitro group may be cleaved from the molecule as nitrite, or reduced to an amino group under either aerobic or anaerobic conditions. Alternatively, the ring may be the subject of reductive attack. Recent work has isolated a *Clostridium bifermentans* able to anaerobically degrade dinoseb cometabolically in the presence of a fermentable substrate. The dinoseb was degraded to below detectable levels, although only a small fraction was actually mineralized to CO_2.

Carbamates such as Aldicarb undergo degradation under both aerobic and anaerobic conditions.

Bioremediation

Groundwater. Atrazine dominated the world herbicide market in the 1980s, and contamination of groundwater has been reported in several locations in the U.S., Europe, and South Africa. Successful biodegradation has been achieved with indigenous organisms in laboratory mesocosms after a lag phase, and once activity was found, it remained. It is clear that intrinsic remediation is likely to lead to the disappearance of atrazine from groundwaters.

If more active treatment is required, such as pump and treat, it is possible that biological reactors will be a cost-effective replacement for activated carbon filters.

Marsh and Pond Sediments. Herbicides and pesticides are detectable in marsh and pond sediments, but intrinsic biodegradation is usually found to be occurring.

Soil. Herbicides and pesticides are of course metabolized in the soil to which they are applied, and there are many reports of isolating degrading organisms from such sites. Little work has yet been presented where the biodegradation of these compounds has been successfully stimulated by a bioremediation approach.

It is a general observation that herbicide degradation occurs more readily in cultivated than fallow soil, suggesting that rhizosphere organisms are effective herbicide degraders. Whether this can be effectively exploited in a phytoremediation strategy remains to be seen.

Military Chemicals

Constituents. The military use a range of chemicals such as explosives and propellants that are sometimes termed "energetic molecules." Generally speaking, modern explosives are cyclic, often heterocyclic, composed of carbon, nitrogen and oxygen, eg; 2,4,6-trinitrotoluene; RDX (Royal Demolition eXplosive; hexahydro-1,3,5-trinitro-1,2,3-triazine); HMX (High Melting eXplosive; octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine); and *N*,*N*-dimethylhydrazine. These compounds are sometimes present at quite high levels in soils and groundwater on military bases and production sites. Bioremediation is a promising new technology for treating sites contaminated with such compounds.

Bioremediation may also be an appropriate tool for dealing with chemical agents such as the mustards and organophosphate neurotoxins, but little work on actual bioremediation has been published.

Biodegradation. Nitrosubstituted compounds are subject to a variety of degradative processes. Under anaerobic conditions TNT is readily reduced to the corresponding aromatic amines and subsequently deaminated to toluene. As shown in the section on hydrocarbons, the latter can be mineralized under anaerobic conditions, leading to the potentially complete mineralization of TNT in the absence of oxygen.

Under aerobic conditions TNT can be mineralized by a range of bacteria and fungi, often co-metabolically with the degradation of a more degradable substrate. There is even evidence that some plants are able to deaminate TNT reductively.

RDX and HMX are rather more recalcitrant, especially under aerobic conditions, but there are promising indications that biodegradation can occur under some conditions, especially composting.

Little work has been reported on the biodegradation of dimethylhydrazine.

Bioremediation

Groundwater. Nitrotoluenes have been detected in groundwater in some areas, and intrinsic remediation may be occurring at some sites by anaerobic degradation.

A commercial technology, the SABRE process, treats contaminated water and soil in a two-stage process by adding a readily degradable carbon and an inoculum of anaerobic bacteria able to degrade the contaminant. An initial aerobic fermentation removes oxygen so that the subsequent reduction of the contaminant is not accompanied by oxidative polymerization.

Soil. Composting of soils contaminated by high explosives is being carried out at the Umatilla Army Depot near Hermiston, Oregon. If this is successful, there are 30 similar sites on the National Priority List that could be treated in a similar way.

Other Organic Compounds. The majority of organic compounds in commerce are biodegradable, so bioremediation is a potential option for cleaning up after industrial and transportation accidents.

Inorganic Contaminants

Nitrogen Compounds

Constituents. Nitrogen-containing compounds are of concern for several reasons. Nitrate levels are regulated in groundwater because of concerns for human and animal health. Ammonia is regulated in streams and effluents as a potential fish toxicant, and any nitrogenous contaminant is a potential problem in water because of its stimulatory effect on the growth of algae. Other nitrogenous contaminants include cyanides in mine waters. Fortunately, all are amenable to biological treatment.

Biodegradation. The biological mineralization of fixed nitrogen is well studied; ammonia is oxidized to nitrite, and nitrite to nitrate, by autotrophic bacteria, and nitrate is reduced to nitrogen by anaerobic bacteria. Urea in sewage and industrial wastes is readily hydrolyzed to ammonia and CO_2 by many bacteria, and cyanides and cyanates are used as sole sources of carbon and nitrogen by some organisms. Wastewater treatment facilities utilize these organisms in assuring that municipal and industrial effluents meet strict water quality standards. See also **Water**; **Wastes abd Pollution**; and **Water Pollution**. On the other hand, ammonia and nitrate are essential nutrients for plant and bacterial growth, so one option is to use these organisms to take up and use the contaminants.

Bioremediation

Surface Water. One example of exploiting biology to handle excess nitrogen in a surface water is the case of the Venice Lagoon in Italy. About a million tons of sea lettuce (*Ulva*) grows in the lagoon annually because of the high levels of nitrogenous nutrients in this relatively landlocked bay. This material is harvested, composted and sold as a low-cost remediation of this problem. In areas where water quality is sufficiently high, growing even more valuable crops, such as nori (*Porphyra*) may be an attractive bioremediation option.

A more constrained opportunity for nitrate bioremediation arose at the U.S.-DoE Weldon Spring Site near St. Louis, Missouri. This site had been a uranium and thorium processing facility, and treatment of the metal had involved nitric acid. The wastestream, known as raffinate, was discharged to surface inpoundments and neutralized with lime to precipitate the metals. Two pits had nitrate levels that required treatment before discharge. Bioremediation by the addition of calcium acetate as a carbon source successfully treated more than 19 million liters of water at a reasonable cost.

Groundwater. One approach to minimizing the environmental impact of excess nitrogen in groundwater migrating into rivers and aquifers is to intercept the water with rapidly growing trees, such as poplars, that will use the contaminant as a fertilizer.

An alternative approach is to add a readily degradable substrate to the contaminated aquifer, in the absence of oxygen, to stimulate bacterial denitrification.

Metals and Metalloids. A wide range of metallic and nonmetallic elements are present as contaminants at industrial and agricultural sites throughout the world, both in ground and surface water, and in soils. They

pose a quite different problem from that of organic contaminants, since they cannot be degraded so that they disappear. Some metal and metalloid elements have radically different bioavailabilities and toxicities depending on their redox state, so one option is stabilization by converting them to their least toxic form. This can be a very effective way of minimizing the environmental impact of a contaminant, but if the contaminant is not removed from the environment, there is always the possibility that natural processes, biological or abiological, may reverse the process. Removing the contaminants from water phases is relatively straightforward, and the wastewater treatment industry practices this on an enormous scale. Pump-and-treat systems that mimic wastewater treatments are already being used for several contaminants, and less complex systems involving biological mats are a promising solution for less demanding situations.

In the past, removing metal and metalloid contaminants from soil has been impossible, and site clean-up has meant excavation and disposal in a secure landfill. An exciting new approach to this problem is phytoextraction, where plants are used to extract contaminants from the soil and harvested.

Bioremediation

Water. Groundwater can be treated in anaerobic bioreactors that encourage the growth of sulfate reducing bacteria, where the metals are reduced to insoluble sulfides, and concentrated in the sludge.

Phytoremediation is not yet being used commercially, but results at several field trial suggest that commercialization is not far away. Perhaps the biggest success to date is the successful rhizofiltration of radionuclides from a Department of Energy site at Ashtabula, Ohio, where uranium concentrations of 350 ppb were reduced to less than 5 ppb, well below groundwater standards, by sunflower roots.

Mine Drainage. Natural drainage water that come into contact with active and abandoned metal and coal mines can become seriously contaminated with a range of heavy-metal ions, and/or often become quite acidic, with a pH near 2. While underground, the water is typically anoxic, and any iron is present as soluble ferrous species. When this mixes with aerobic surface water, the iron precipitates as bright orange ferric hydroxide, and this can have a serious environmental impact. In recent years it has become clear that the environmental impact of acid mine drainage can be minimized by the construction of artificial wetlands that combine geochemistry and biological treatments. These systems are being designed for a range of wastewaters, most of which fall outside the scope of this article.

Soil. The results of the first reported field trial of the use of hyperaccumulating plants to remove metals from a soil contaminated by sludge applications were positive. However, the rates of metal uptake suggest a time scale of decades for complete cleanup. Trials with higher biomass plants, such as *B. juncea*, are underway.

The bacterial reduction of Cr(VI) to Cr(III) is also being used to reduce the hazards of chromium in soils and water.

BIOSATELLITE. An artificial satellite which is specifically designed to contain and support humans, animals, or other living material in a reasonably normal manner for an adequate period of time and which, particularly for human and animals, possesses the proper means for safe return to the earth.

BIOSENSORS. The detection of trace and low levels of biologically active substances is among the most significant and challenging analytic technologies. See also **Trace and Residue Analysis**. Any discrete sensing device that relies on a biologically derived component as an integral part of its detection mechanism is known as a biosensor. See also **Biopolymers**.

All biosensors are composed of two basic parts, the molecular recognition component and the transducer component. The molecular recognition component is typically a complex chemical system usually extracted or derived directly from a biological organism. The function of the molecular recognition component is to interact specifically with a target compound, i.e., the chemical to be detected. The molecular recognition component must be capable of discerning the presence of a target in a solution containing possibly hundreds of other compounds, some of which may have molecular structures closely resembling that of the target. The term selectivity is used to quantify the degree to which a molecular recognition system responds specifically to a target while rejecting compounds having related molecular structures. There are three principal classes of molecular recognition components used in biosensors: enzymes or catalytic proteins; immunoglobins, which are biological macromolecules that selectively bind to foreign substances invading an organism; and chemoreceptors, biomolecular units responsible for sensory reception in living organisms. Each class has advantages and disadvantages, and each class comprises a vast number of highly selective possible molecular recognition components.

Once the molecular recognition component interacts with its target, a user-readable signal must be generated. This is the purpose of the transducer component. Ideally, the generated signal should not only report the presence of target but should also relay information concerning the amount or concentration of target compound in the test solution. As of this writing, there were four main types of analytical transducer components employed in biosensors: optical, electrochemical, field effect transistor, and piezoelectric.

The term sensitivity is used to quantify the ability of a biosensor to reliably report target level. There are two separate uses of the term. First, the detection limit of a biosensor is the lowest concentration of target for which the biosensor provides a reliable, reproducible, and unambiguous response. Increasing the sensitivity of a biosensor frequently refers to decreasing the biosensor's detection limit. Second, sensitivity can also refer to the smallest change in concentration from some nominal level of target compound that the biosensor can unambiguously report. Increasing sensitivity in these latter terms is usually a more difficult task than decreasing the detection limit.

Biosensor design involves consideration of many factors. Molecular recognition components are frequently large complex biomolecules or biological macroassemblies and usually perform efficiently within narrow ranges of pH, temperature, and ionic strength. Degradation and the limited lifetimes of biologically derived components can be important. Additionally, immobilization of enzymes sometimes results in decreased target activity. Factors influencing the selection of an appropriate transducer component include compatibility with the molecular recognition component and the environment in which the biosensor is to be used. Development and optimization of biosensor techniques is a rapidly growing research area.

Biosensor designers are striving for lower detection limits, higher sensitivity, greater selectivity, and lower occurrences of false-positive signals. The detection limit for a biosensor is related to the nature of both the molecular recognition component and the transducer component. In general, antibodies and chemoreceptors are well-suited for low detection limit biosensors because of the high binding constants for target molecules.

In general, low level detection is masked by the noise level inherent in any measuring device. Electrochemical methods are susceptible to electrical interference from external sources, variations in reference electrode parameters resulting from aging or contamination, and interference from redox contaminants in the test solution.

An ingenious method of decreasing detection limits in biosensors that is frequently employed is enzyme amplification. An example is enzyme multiplied immunoassay technology (emit).

BIOSOLIDS. Wastewater treatment processes remove organics, inorganic materials, and contaminants in sludge. Biosolids are treated municipal wastewater sludge that can be beneficially used, especially as a soil amendment, in accordance with standards.

The Water Environment Federation (WEF) has adopted a policy of encouraging the use of the word "biosolids" in place of sludge to promote public acceptance of reused materials. Land application of biosolids has been and continues to be successfully implemented by many countries. Many countries have rules and regulations associated with biosolids reuse and disposal. Almost all rules are based on reducing pathogens and pollutants. However, rules and regulations vary in different countries. Criteria and methods of obtaining results to determine the use of biosolids also vary.

The United States EPA Standards (US EPA, 1993, 1995) for using sludge includes pathogen requirements, vector attraction reduction requirements, and pollutant ceiling concentrations. In accordance with them, two classes of requirements — Class "A" and Class "B" were accepted as rules. To achieve Class "A" (pathogen) requirements, either the density of fecal coliform bacteria in the sludge shall be less than 1000 Most probable number (MPN) per gram of total solids, or the density of *Salmonella* sp. bacteria shall be less than 3 MPN per 4 grams of total solids. In addition, the sludge must contain less than one unit of plaque-forming virus and less than one helminth ova per 4 grams of total solids.

Class "B" sludge product must meet one of three alternative requirements. In the first of these, the geometric mean of the density of fecal coliform (expressed either by MPN or colony-forming units per gram of total solids) for seven samples must be less than 2,000,000. The geometric mean is the antilogarithm of the arithmetic average of the logarithms of seven samples. Alternatively, the sludge may be classified as Class "B" by being treated by a process to significantly reduce pathogens (PSRP) or by a process determined to be equivalent to PRSP by the permitting authority.

Class "A" sludge is prone to regrowth of pathogenic bacteria, such as *Salmonella* sp., after treatment because it lacks an adequate density of competitive organisms. Concerns for regrowth led to several additional requirements. First, pathogen reduction must be achieved prior to or at the same time that certain vector attraction reduction requirements are met. Second, pathogen density requirements must be met when the biosolids are used or disposed of, not when sludge is treated. Third, Class "A" biosolids applied to the land for vector attraction reduction must be applied within 8 hours after discharge from the pathogen treatment process.

Class "B" biosolids cannot be sold or given away in a bag or other container for land application. Biosolids, which meet Class "B," can be applied to agricultural land, forests, public contract sites, or reclamation sites. Land application of Class "B" has restrictions for the harvesting of crops and turf, grazing of animals, and public access.

These restrictions are designed to provide time for the natural environment to reduce the pathogenic organisms in the biosolids. Food crops that touch the biosolids/soil mixture and are aboveground cannot be harvested for 14 months after application of biosolids to land. Root crops cannot be harvested for 20 to 38 months after biosolids application. In this case, the lowest time period applies if biosolids remains on the land surface for 4 months prior to incorporation into the soil, and the higher value applies when it does not. Class "A" and Class "B" biosolids have some vector attraction reduction requirements for land application.

The disposal alternatives are based on the treatment level provided. The most common methods for achieving Classes "A" or "B" biosolids include digestion, composting, thermal drying, and alkaline stabilization.

Digestion

Several sludge digestion technologies that consist of anaerobic and aerobic processes are widely used.

Anaerobic Digestion. Anaerobic digestion is a biological process of reducing volatile solids by microorganisms in the absence of oxygen; it reduces odor and pathogen content. Digesters are cylindrical reservoirs with conical bottoms; the upper section of the reservoir has a sealed cover with a device for collecting gas. One-stage and two-stage digesters are in use. In two-stage digesters, the first stage has covered heated reservoirs, and the second stage has open, unheated reservoirs.

Two types of anaerobic digestion processes are in use — *mesophilic* and *thermophilic*. Mesophilic processes function in the temperature range of 32–35 °C (90–95 °F). The thermophilic process is operated at a higher temperature 50–55 °C (122–131 °F) to reduce organic solids and pathogen content further. The process can use conventional standard rate and high-rate digesters with solid retention time from 30–60 days to 10–20 days. To produce Class "B" biosolids, digested sludge has to meet one of the following: reduce volatile solids by a minimum of 38%, or demonstrate that further anaerobic digesting of a portion of the sludge in a bench-scale lab unit for 40 additional days at a temperature between 30 and 37 °C (86 and 99 °F) will reduce the volatile solids by less than 17%.

The end products of anaerobic digestion are biosolids, gas, and water. The following gas composition can be expected: methane — 60 to 75%; carbon dioxide — 16 to 40%; nitrogen, hydrogen, and oxygen — 0.4 to 6%. The average heat of combustion of this gas is 21 million joule/m^3. Depending on the chemical composition of the sludge, the liberation of gas varies from 5 to 20 m^3 per m^3 of sludge or 1 m^3 for every 1 kg of a disintegrated sludge's organic content.

Anaerobic digestion requires energy in the form of heat and electricity. Supplying this energy can be expensive unless part of the energy required is received directly from using the gas. When less than 10–12 m^3 of gas is liberated per 1 m^3 of sludge, the resulting heat balance may be negative. If the gas obtained is in excess of 12 m^3 per 1 m^3 of sludge, it may be used in boilers, heating systems, and so on.

Methane is characterized by explosion hazard and may poison people, if the gas leaks. The volume of gasholders is determined in accordance with gas production and the demand schedule. The volume of gasholders is approximately equal to 2–4 hours of gas production.

Aerobic Digestion. Aerobic digestion is a process of oxidation of the organic part of sludge by microorganisms in special tanks in the presence of oxygen (air aeration of sludge). Aerobic digestion has been widely used in wastewater treatment plants (WWTP) for many years. The purpose of aerobic sludge digestion is to stabilize raw sludge and produce biosolids for further treatment and disposal. Equipment for aerobic digestion is simpler, with in design and operation than that for anaerobic digestion. The more useful sludge aerobic digestion processes are conducted in open structures of the aeration tank type. The duration of the volatile part of solids oxidation depends on the food/microorganism ratio, temperature, intensity and quantity of aeration, and also on wastewater composition and technological demand. This process is more useful for digesting and stabilizing thickened activated sludge.

The detention time to reduce volatile solids and stabilize a mixture of waste activated sludge and raw primary sludge may be 10–15 days at an operating temperature of 20 °C (68 °F). Traditionally, digesters have been designed for a detention time of 20–30 days. However, to meet Class "B" sludge regulations by aerobic digestion, Federal Regulations (40 CFR 257) require detention times of 40 and 60 days at temperatures of 20 °C and 15 °C (68 °F and 59 °F), respectively, and reduction of volatile solids by a minimum of 38%. Long aerobic digestion times require large tank volumes. To reduce tank volumes, the solids concentration can be increased by gravity, belt, or drum thickeners.

Aerobically digested biosolids should be settled for 1.5–5 hours in a sedimentation zone inside the aeration tank or settling in sedimentors. The supernatant BOD is about 100 mg/L, and the COD varies from 350 to 700 mg/L. The moisture content of the biosolids is 95–98% after sedimentation.

Oxidation of the organic part of sludge releases about 3.6 kcal of heat per gram of volatile suspended solids (VSS) in aerobic autoheating mesophilic digestion or autothermal thermophilic aerobic digestion. Temperature control is important in both processes. These processes use heat, created by biochemical oxidation of the organic substances by air introduced into the reactors. The processes are realized in hermetically sealed reactors. The heat balance has to take into account heat loss to surroundings, effluent gas, effluent sludge, and so on.

Autothermal thermophilic aerobic digestion (ATAD) systems for sludge stabilization and disinfection include two hermetically sealed reactors which can be operated with an existing anaerobic digester (prestage ATAD)

or operated as conventional ATAD. By using the ATAD process for heat balance, activated sludge has to be thickened to 5% or more of dry solids using belt or rotary drum thickeners. Technological schemes include waste-activated sludge holding and buffer tanks, thickeners, pumps, heat exchangers, reactors, treated sludge holding tanks, and communications. Depending on the temperature and process duration, ATAD can be used to produce Class "B" or "A" biosolids. Class "A" biosolids should be heated to 55–60 °C (131–140 °F) and aerated for about 10 days. Class "B" aerobic and anaerobic digested biosolids may be converted to Class "A" by maintaining a temperature of at least 70 °C (158 °F) for a minimum of 30 minutes. This can be done by inserting hot air or gases directly into the digested biosolids or by using heat exchangers.

Composting

Composting of domestic waste and manure has been used for thousands of years. However, the production of compost from wastewater sludge of large-scale municipal wastewater treatment plants began in the 1960–1970s.

Composting can be performed as aerobic or anaerobic biothermal processes which release heat during the decomposition of organics. Aerobic biothermal processes release almost 30 times more heat than anaerobic processes. That is why aerobic processes are used more often. The composting process reduces the organic material in the sludge by approximately 25–30%. During composting, the heat generated by the decomposition of the organic portion of the sludge, reduces the moisture content of the sludge, stabilizes the sludge, and renders the residual harmless by transforming it into usable biosolids.

The heat generated by decomposition of 1.0 kg of organic material averages 20–21 million joules (Mjoule). This generated heat drives the biothermal process and moves the composting process from the mesophilic phase (25 to 40 °C, 77 to 104 °F) to the thermophilic phase (55 to 65 °C, 131 to 149 °F). Most pathogens are destroyed during the thermophilic phase.

The generated heat also facilitates the evaporation of moisture. Approximately 4.0 Mjoule of heat will evaporate 1.0 kg (2.2 lbs) of moisture (taking into account heat losses and heating of the compost material). Thus, decomposition of 1.0 kg (2.2 lbs) of organic material facilitates the removal of approximately 5.0 kg (11 lbs) of moisture from the sludge (21 Mjoule/4 Mjoule/kg of water).

Before composting, it is necessary to dewater sludge. Dewatering reduces the volume of sludge, and it also decreases the amount of moisture to be evaporated by the composting process.

The aerobic process can be performed by using different systems — windrow, aerated static piles, or in-vessel. Sludge is composted together with bulking materials, such as saw dust, wood chips, peat, paper product waste, and ready compost, which provide the mixture with the necessary moisture, porosity, and carbon content.

For vector attraction reduction requirements and to achieve Class "B" biosolids during composting, the temperature has to be above 40 °C (104 °F) for a minimum of 14 days and average more than 45 °C (113 °F) for the same period. To obtain Class "A" compost, the US EPA requires that the temperature in the piles have to be at least 55 °C (131 °F) for 3 days.

Windrow piles or trenches are effective, but mixing and turning does not provide enough air, that is why anaerobic conditions (sometimes) take place in these devices, which generates odors. More often aerated static pile composting is used. Piles have been made by mixing dewatered sludge with wood chips or saw dust. Arrangements of dewatered sludge and amendments prior to mixing follow recycled wood chips (or saw dust) on the floor, dewatered sludge on the top, or when fresh, wood chips (or saw dust) or recycled compost. To prevent heat loss and protect against insects and rodents, piles are covered by ready compost.

In aerated static piles, perforated pipes mounted underneath the composting pile provide aeration. Pipes are covered with layers of sand, gravel, or bulking material and are connected to blowers.

Aerated static pile composting is an effective process. It is easy to operate and does not require high personnel qualification. Compost is a dry, disinfected, and stabilized product. However, the speed of the process depends on several factors, such as bulking materials; proportion of bulking materials to dewatered sludge; efficacy of mixing bulking materials with dewatered sludge; temperature, moisture, and porosity of the mixture; mass of the mixture being composted; quantity of air and duration of aeration; correction between C and N; quantity of recycling compost and bulking material, and toxicity to biological decomposition.

The moisture content of mixed sludge-bulking material has to be 60–67%. The quantity of air is 10–25 m^3/hour per ton of volatile solids. Increased air allows an increase in process speed, but excess air decreases the process speed and temperature. Aeration begins 5–10 days after starting the process and lasts 25–30 days for 8 hours every three days. The index of aeration is the concentration of CO_2. When the concentration of CO_2 increases to more than 7% of gas volume, inhibition of microorganisms and a decrease in temperature occur. At the beginning of the process, the carbon to nitrogen (C:N) ratio is 30:1–34:1 in a pile with saw dust and 25:1–27:1 in a pile with ground bark. Compost is cured for 1–3 months. In the United States, more than 200 composting facilities are in operation now, mostly aerated static piles. But windrow and in-vessel composting also takes place.

Windrow piles are turned with mobile equipment every 3–5 days until the temperature is maintained at 55–65 °C (131–149 °F) and composted for a period of 3 to 5 weeks, when cured and stored in piles for 1–2 months. The process is based on constructing a windrow from a mixture of dewatered sludge, bulking agent, and recycled compost that provides composting material of proper moisture content, porosity, and carbon source for microorganisms.

Composting processes such as windrow, static piles, aerated static piles, and different types of in-vessel (vertical towers, vessels, reactors, containers, and so on) are widely used in Europe, Japan, and other countries. In-vessel composting processes are accomplished inside enclosed containers that provide a completely controlled environment, temperature, aeration, and odor control. However, in-vessel systems are more complicated and expensive than windrow or aerated static piles and require qualified personnel.

Thermal Drying

Thermal drying is designed to disinfect and decrease the weight and volume of wastewater sludge. Thermal drying permits economical sludge transportation from treatment plants and subsequent use.

Thermal drying of sludge is conducted in drying systems consisting of a drying device (dryer) and auxiliary equipment, which includes furnaces with a fuel supply system, feeders, cyclones, scrubbers, blowing equipment, conveyors and bins, as well as monitoring and measuring instruments and automatic control equipment.

To reduce fuel required, sludge should be dewatered before thermal drying by using belt process, centrifuges, or plate presses. For thermal drying of sludge, use fluidized bed dryers, drum dryers, opposite jet dryers, dryers with peripheral discharge of the dried sludge, or Pelletech drying systems. In dryers, the drying temperature should reach 500–800 °C (932–1,472 °F), and drying time is approximately 10–15 minutes.

The Pelletech dryer is a vertically oriented multistage unit that uses steam or thermal transfer fluid in a closed loop to achieve 90% or greater dry solids content in the product. This process minimizes formation of dust and oversized chunks. Pelletizing and drying involves heat and mass transfer, mixing, combustion, conveying, classification, and evaporation.

Thermal dryer sludge is a Class "A" biosolid when sludge achieves 75% dry solids concentration, if no unstabilized primary is present, and 90% of dry solids content, if unstabilized primary sludge is present, by direct or indirect contact with hot gases. Either the temperature of the sludge particles exceeds 80 °C (176 °F) or the wet bulk temperature of the gas in contact with the sludge as the sewage sludge leaves the dryer exceeds 80 °C (176 °F).

The thermal drying process exceeds Class "A" biosolids regulations and can be used for soil improvement without additional restrictions; the solids can be bagged or sold in bulk as fertilizer to landscape contractors or the general public.

Alkaline Stabilization

To produce biosolids that meet pathogen and vector attraction reduction requirements, wastewater treatment plants often use alkaline stabilization. For sludge stabilization, which meets Class "A" or "B," quicklime or hydrated lime are used. Lime is added to sludge before or after dewatering. If quicklime is added to sludge, it initially reacts with water to form hydrated lime. This reaction is exothermic and releases approximately 15,300 cal/g mole (27,500 Btu/lb/mole). The reaction between quicklime and carbon dioxide is also exothermic, releasing

approximately 43,300 cal/g mole (78,000 Btu/lb/mole). To achieve Class "A" pathogen reduction, the quantity of added lime is determined so that the pH of the sludge and lime mixture is raised to 12 or greater for 72 hours; the temperature of the sludge during this period must be higher than 52 °C (126 °F)for 12 hours or longer. In addition, air-dried resultant biosolids have to achieve greater than 50% solids content. This process is often called sludge pasteurization. The lime pasteurization process provides a higher level of pathogen reduction than lime stabilization and the result is biosolids that meets Class "A" requirements.

For vector attraction reduction that meets Class "B," the mixture of sludge and lime has to be raised to pH 12 for at least 2 hours and remain over pH 11.5 for an additional 22 hours, all without further alkali addition.

Disinfection of sludge with quicklime or hydrated lime is widely used in Europe to reduce odor, pathogens, and putrefaction of the sludge. Lime stabilization can be part of a sludge conditioning process prior to dewatering (prelime stabilization) or following a dewatering step (postlime stabilization). As a rule, lime is stored in silos and mixed with sludge by various types of mixers.

Conclusion

Biosolids are treated wastewater sludge that can be beneficially used as a soil amendment. When considering the use of biosolids, how and where biosolids may be used and how they should be prepared for use corresponding to the requirements of Standards should be determined.

Several processes for sludge treatment such as different methods of digestion, thermal, biothermal, or chemical treatment provide reduction of pathogens and vector attractions to achieve Class "A" or "B" biosolids. Aerobic and anaerobic digestion of sludge are widely used processes of sludge stabilization and produce biosolids that meet Class "B" sludge regulations. Autothermal thermophilic digestion systems operated in hermetically sealed reactors allow production of Class "A" biosolids.

Thermal drying, lime stabilization, and lime pasteurization are used to destroy pathogens, eliminate odor, reduce most of the water content and the volume of sludge, and lower transportation costs of biosolids. These processes are in use for Class "A" or "B" biosolids.

Composting is an effective way of stabilizing and reducing pathogens in sludge. Many utilities use wastewater sludge composting systems, such as windrow, aerated static piles, and in-vessel.

Composting delivers high quality product, which has macro-and micronutrients and can be used as a soil conditioning material, amendment, or fertilizer — either as Class "A" or "B."

Biosolids, after appropriate treatment, may be used as a fertilizer on agricultural lands, forests, public contact sites, reclamation sites, rangeland, pastures, lawns, or home gardens. It should be determined if Class "A" or Class "B" pathogen requirements can be reached and also if the sludge meets one of the vector attraction reduction criteria. After that, pollutant concentration and doses of embedding biosolids in soils should be determined.

Extensive use of dewatered and disinfected biosolids received from municipal wastewater treatment plants as fertilizers will contribute to the solution of the problem of their effective, economical, and ecologically acceptable removal and disposal.

BIOSPHERE. All the area occupied by, or favorable for occupation by, living organisms, including parts of the lithosphere, hydrosphere, and atmosphere. See **Ecology**.

BIOSTRATIGRAPHY. The classification, correlation, and interpretation of stratified rocks on the basis of the fossils that they contain.

BIOSTROME. A geologic term for layers, beds, or strata composed of calcareous fossil shells that form coquina, or shell-limestone. The term biostrome is primarily intended to distinguish shell-limestone from bioherms, or typical coral reefs.

BIOTECHNOLOGY (The History). Biotechnology came to the attention of policy makers as a key technology for the future at the end of the 1970s. It was a time when the rising price of oil and global competition was calling into doubt the future prosperity of traditional industries. Information technology, materials and biotechnology were widely seen as bases for future prosperity. Such was the faith in the category of biotechnology that little regard was given to its actual meaning. The popular concept confounded two concepts: the idea of the application of biology or life processes in general, on the one hand, and, on the other, the application of specific new techniques relating to recombinant DNA and monoclonal antibodies.

The confusion extended to muddle over the key products that would follow. Certainly, what made biotechnology seem a potential counterpart to information technology in a third industrial revolution were the recent advances in molecular genetics. They seemed to offer the possibilities of making industrially proteins identical to those produced in the normal human body. These might be used to compensate for single gene genetic defects affecting as many as 3% of the population while others such as interferon might be used to boost the body's defenses against such hitherto formidable foes as cancer. There was also hope that industrially useful materials such as alcohol, plastics or ready colored fibers might be made in plants, so the attractions of a potentially new agricultural regime might be as great as the implications for medicine. At a time of concern over agricultural subsidies such hopes were doubly welcome. Indeed the agricultural benefits sometimes overshadowed the medical implications.

However, furor over the agricultural use of genetically modified organisms meant a growing distinction between agricultural and medical aspects of biotechnology. The continuing change in the anticipated future meant that there would be continuing uncertainty as to the essential roots in the past. What they shared was a sense of the historic significance of the changes that were already occurring.

On 27 June 2000, the British Prime Minister and the President of the United States in a linked press conference announced the completion of the draft map of the human genome. The Director of Britain's Wellcome Trust was quoted as suggesting that achievement was comparable in importance to the development of the wheel. Thereby he was integrating the event not just within the history of technology in general but also within the history of claims for biotechnology. Since the beginning of the twentieth century there had been a belief that the implications of harnessing life to technology would be momentous. Indeed the grandeur of expectations has been a defining feature of biotechnology over time. See also **Human Genome Project (The)**

The historiography of this vision of biotechnology has often been cast as running back through the discovery of recombinant DNA techniques in 1973, the discovery of the structure of DNA in 1953, through the studies of genetics by Thomas Hunt Morgan in the 1920s to Mendel's pioneering studies of the genetics of the pea in the nineteenth century. It was a solidly scientific lineage. However, biotechnology was an established industry before the impact of molecular genetics. It was associated with the most important drugs ever made, the antibiotics and hopes for world-shaking products such as starvation-curing single-cell protein, and energy-producing gasohol. The confusion between the two visions of the radically

new and the well established was sometimes resolved by differentiating between "old" and "new" biotechnology. This distinction, made by the U.S. Office of Technology Assessment, was too abrupt. Although it served to distinguish the potential new industry of protein manufacture from the mature if unproblematic historic microbiological industries such as brewing whose ancestry could be traced to the Babylonians, links between the twentieth century fermentation-based industries were obscured. This account suggests that rather than seeing the history of biotechnology as based on the history of genetics, it is more accurate to say that biotechnology was rescued by genetics. See also **Drug Discovery (The History)**.

This account has three parts, dealing with three overlapping periods. It deals first with the history of biotechnology as industry and as concept from its roots at the end of the nineteenth century to the impact of molecular genetics in the 1970s. Secondly it treats the quarter century from 1965 to 1990 during which the potential of molecular genetics was being negotiated. Thirdly it concludes with the human genome program.

Concept and Industry 1870–1940

The so-called *second industrial revolution* of the period 1870–1914 is often associated with the development of formal research and development, and the application of science to new industries. The emergence of the chemical industry is widely taken as emblematic. Yet the development of microbiological industries might also be more frequently cited. The articulation of the germ theory by Pasteur enabled the formulation of a theory of brewing and other fermentation processes. Across Europe the implications were explored as such traditional businesses as beer, wine and cheese making were subjected to applied science. Even before the work of Pasteur the general term zymotechnology had been used to designate the variety of fermentation industries. Now it took a leap forward. In Copenhagen Emil Christian Hansen attacked the problem of erratic brewing at the Carlsberg brewery and founded the pure yeast process. His contemporary Alfred Jørgensen published a widely used textbook on zymotechnology and at his private institute of fermentology taught over seven hundred students from many countries over a period of thirty years. His pupil Orla Jensen would specialize in cheese making rather than brewing, but continued the vision of an integrated discipline. Before World War I he pioneered a course in 'biotechnical chemistry' at Copenhagen's polytechnic. See also **Fermentation**.

Impending and then actual war accelerated the use of fermentation technologies to make strategic materials. In Britain a process to ferment butadiene for synthetic rubber production was adapted to make principally acetone as a plasticizer for explosives. This work was begun by a large consortium led by William Perkin Jr. in Manchester, England, including his Manchester-based colleague Chaim Weizmann, and Auguste Fernbach at the Pasteur Institute in Paris. When Weizmann developed his own improved system, it was eagerly taken up by the British government, supplanting the product of the international collaboration. The process was technically important as the first industrial sterile fermentation, and strategically important for munitions supplies. There is, however, no truth in the story that Lord Balfour's Declaration of 1917 promising Palestine to the Jews was made in gratitude. In Germany scarce oil-based lubricants were replaced by fermentation-derived glycerol developed by Wilhelm Connstein and Karl Ludecke in Berlin and animals were fed yeast grown with the aid of the new synthetic ammonia.

In wartime Hungary, the problems of animal-feeding at a time when humans were crying out for scarce protein led to a search for efficiency and the developing concept of the animal-machine which underpinned what the engineer Karl Ereky called *biotechnology*. Its use in a series of his publications from 1917 to 1919 can be considered the first coinage of the word.

Ereky's concept was taken up in Germany where it was adapted to describe the use of microorganisms such as yeast as machines. There and elsewhere the postwar years saw many attempts to make industrial use of agricultural materials. Not only was it hoped that thereby cheaper products could be obtained, but also agricultural crisis would be stemmed. In the United States this philosophy led to the so-called *Chemurgy Movement*. The most widespread application was the production of ethanol fuel for internal combustion engines, from agricultural waste. More sophisticated products included the soybean-based plastic promoted by Henry Ford as a material for car bodies. The culmination of this tradition, which would also lay down the basis for the next generation of biotechnology, was the development of penicillin.

The first of the antibiotics was detected and named by Alexander Fleming in London in the 1920s. The technique of deep fermentation and the successful mould strain were, however, pioneered in the Northern Regional Research Laboratory in Peoria, Illinois, set up in the wake of chemurgic enthusiasm in the 1930s. Despite the belief of chemists that they would quickly synthesize the new medicine, it was produced more economically by fermenting mould in the newly developed stirred tank fermenter and by 1944 the new wonder drug was widely available, setting a new standard for medicine and a super-star success for biological technology. See also **Fleming, Sir Alexander (1881–1955)**; and **Penicillin (The History)**.

Such achievements as fermentation alcohol, acetone and even penicillin were accomplished by people who believed that fermentation could make a vital contribution to technological change but were not themselves philosophers. In parallel with their work, thinkers coming out of the biological community were reflecting on the significance of using living beings as machines.

Evolutionary Theory: Engineering Heredity. From early in the twentieth century a cluster of approaches, theories and styles that could be described as neo-Lamarckian provided the context for hope and indeed expectation that the intrinsic powers of humanity could be extended and improved through scientific action. These ideas were closely linked to eugenics. While today eugenics is associated with murder, many neo-Lamarckians had hoped that humanity could be improved by positive action. A sense of impending technological revolution provided the context in which Lamarckian biological ideas about the improvement of species were transformed into conceptions about the self-improvement of mankind and new industrial modes. That translation was typically expressed through appeals to a lay audience. Three nodes in a network of thinkers and writers were particularly influential. Many of the men I shall deal with have been forgotten and have not generally been considered part of the apostolic traditions of either biology or technology. Where they have been recalled, the links between them have been overlooked. See also **Lamarck, Jean-Baptiste Pierre Antoine de Monet de (1744–1829)**.

The first node includes both the Austrian experimental biologist Paul Kammerer and his friend the sociologist Rudolf Goldscheid. The second node includes the Hungarian biologist Raoul Francé, the Scottish biologist Patrick Geddes and his collaborator J. Arthur Thomson. As a third node I would point to men who took some of the ideas identified by those others but were far from neo-Lamarckian themselves: the British biologists and popularizers of science, Julian Huxley and Lancelot Hogben. See also **Huxley, Julian Sorrell (1887–1975)**; **Kammerer, Paul (1880–1926)**.

Paul Kammerer would win infamy as a fraud who painted toads to make them appear as if they had changed color. He was exposed in 1923 and subsequently shot himself. Yet he had been very popular. A Soviet film was even made about his life. Kammerer's concept of a new technology defining a new age was put at length by his close friend Rudolf Goldscheid, the Viennese Marxist feminist polymath. He was concerned with people as valuable resources. To Goldscheid it was scandalous to see the degradation and waste of lives and resources which poverty and poor conditions led to. He wished to see an upgrading of the human resource and Lamarckian biology suggested a way. He had been a leading spirit in the establishment of Austria's principal sociological society and with Kammerer he set up its social biology section. In his key work of 1911, *Höherentwicklung und Menschenökonomie*, subtitled *Grundlegung der Sozialbiologie*, he suggested that what he called *Biotechnik* would be the way of the future. In almost the same words as Kammerer would use, he suggested that *Biotechnik* would become the defining technology of the twentieth century. It would include eugenic measures but also birth control for mothers and control of drink and poverty. Increasing quality would make up for declining quantity.

Goldscheid and Kammerer had drawn upon a link between Lamarckian biology and the improvement of humankind itself. Others derived the possibility of improving biological organisms and their greater perfection compared to mere manmade crude devices. This old theme in western culture was given a name by the Hungarian idealist Raoul Francé. During World War I he developed his own concept of *Biotechnik* which he thought should dominate the development of later engineering. His work was well known in Germany with books selling in the millions.

Although Francé's work was hardly known in England directly, within a few months of the publication of his classic work *Bios* in 1920, the Scottish biologist and town planner Patrick Geddes was using the word

biotechnics apparently for the first time. Geddes too sought to link life and technology. Before World War I he had characterized the technological evolution of humankind as a move from the paleotechnic era of coal and iron to the neotechnic era of chemicals, electricity and steel. Like Francé, Goldscheid and Kammerer, after the war, he detected a new era based on biology, the biotechnic era. His was perhaps a more practical image than Francé's; it included for instance agriculture and eugenics rather than completely new kinds of mechanics. However, for Geddes too biotechnics was part of the evolution of mankind. Through his younger friend, the writer Lewis Mumford, Geddes would have an enormous effect: *Technics and Civilization*, which promoted Mumford's vision of the Geddesian evolution, is itself a founding volume of the modern historiography of technology.

A thrusting new English generation of experimental biologists with a special interest in genetics, including J. B. S. Haldane, Julian Huxley and Lancelot Hogben, also promoted a concept of biotechnology. Even though they had little time for formal neo-Lamarckianism, all three were on the left politically, and wanted their science of genetics to be both useful and comprehensible to the wider public. Each believed that by means of biological invention humankind could improve itself. The previous generation had already made it axiomatic that the twentieth century would be the era of the bioengineering revolution. The only question outstanding was how that would be implemented. Huxley, perhaps following Goldscheid, foresaw a combination of social and what he called *biological engineering*, based upon eugenics. It was this vision that underlay his claim of 1936 that: "Biology is as important as the sciences of lifeless matter, and biotechnology will in the long run be more important than mechanical and chemical engineering."

To the modern reader nurtured on the vision of biotechnology's prospects as predicated upon recent discoveries, this claim may seem remarkably farsighted, but even then it was already a traditional assumption. To Hogben, following Geddes, these were predominantly to be seen in the possibilities of engineering plants through breeding. He tied the progressivism of biology to the advance of socialism. Hogben and Huxley may have been erstwhile radicals but through their popular works, such as Hogben's *Science for the Citizen* which would become the possession of every middle-class home in Britain, they were already becoming some of the best known scientists in the land. The reaction from Julian Huxley's brother, the writer Aldous Huxley, expressed in his book *Brave New World*, was equally seminal as the key work of the age pouring scorn on scientism.

Bioengineering After World War II. The pragmatic and the programmatic strains of biotechnic thinking of the 1930s came together in the years after World War II. Medicine, energy and the environment were each seen to be served by a potentially powerful new technological paradigm. The manufacture of antibiotics and then steroids by means of fermentation technologies grew enormously. This provided a context for the formalizing of biotechnology as a distinct applied science. The journal *Biotechnology and Bioengineering* was christened in 1961. During the 1960s food based on single-cell protein grown in fermenters on oil or glucose seemed to visionary engineers and microbiologists and to major companies to offer an immediate solution to world hunger. British Petroleum, Shell, Hoechst, Esso [Exxon], Rank Hovis McDougall and ICI as well as Japanese and Soviet enterprises made major investments. Most would lose heart as consumers rejected the idea of many of the novel foods and the price of oil rocketed in the mid-1970s. Nonetheless in the Soviet Union fermentation based protein would be a major source of animal feed through the 1980s.

Genetic Engineering

Even more ambitious were the possibilities for human modification anticipated from the early 1960s. At meetings in London in 1962 and Ohio in 1963, biologists and doctors were debating the implications of human genetic engineering long before it was in practice possible. The production and administration of proteins that would compensate for the ravages of genetic disease seemed both possible and economically important. Genetic disease would, it was hoped, be controlled as bacterial disease was already being controlled by antibiotics. Biologists felt they had a responsibility to anticipate problems and to engage the public in advance of the explosion of "social dynamite" (to use a phrase adopted by Joshua Lederberg in a 1962 letter). See also **Lederberg, Joshua (1925–Present)**.

During the early 1970s what had been science fiction became fact, as the use of DNA synthesis, restriction enzymes and plasmids were integrated. In 1973 Stanley Cohen and Herbert Boyer successfully transferred a section of DNA from one *Escherichia coli* bacterium to another. At a conference in Asilomar, California, molecular biologists agreed they would hold off further work until regulations were in place to prevent danger to workers or the environment. The moratorium lasted until 1976. See also **Cohen, Stanley (1922–Present)**.

The debates of the mid-1970s about the future of genetic engineering were polarized between those who anticipated terrible environmental and ethical consequences and those who counterbalanced the speculative risks with equally speculative benefits. The arguments were recited in a series of reports, enquiries and commissions in the USA and Europe which could be said to have themselves defined modern biotechnology. Although the products were clearly in the somewhat distant future, the issue of regulation was immediate. The need to debate a regulatory regime before enquiries, courts and parliaments tended to polarize the issues.

The late 1970s were a time when environmentalists were successfully defying the nuclear industry, the rising price of oil was challenging the traditional mainsprings of industrial growth and the computer was already an icon of a new silicon-based industrial revolution. This was the context in which biotechnology was cast as potentially either another dreadful threat or a source of industrial redemption. The ambivalence of government-based regulators was mirrored by stock market investors alternately enthused and despondent about the prospect of specialized biotechnology companies.

The phrase genetic engineering was coined in the early 1960s possibly by Arthur Tatum to reflect the possible ways in which the human frame itself might be affected by molecular biology. In the 1980s and 1990s the phrase and its relative genetic modification were used to describe recombinant modification of plants and bacteria. See also **Genetic Engineering**.

A New Industry. In 1979 a stock market analyst at the company E. F. Hutton applied the label "biotechnology" to the small group of companies anticipating a bounty from the use of genetic engineering to make therapeutic proteins. The hopes that the protein interferon made biotechnologically would cure cancer drove up stocks of biotechnology companies in the early 1980s. Other technologies sustained similar hopes. The development of monoclonal antibody technology growing out of the Nobel Prize winning work of Georges Köhler and César Milstein in Cambridge seemed to offer new prospects for precise attacks on particular cells. This raised hopes both for commercial diagnostics and therapy. Diagnostically it has been a great success, simplifying for instance pregnancy testing. However, therapeutically its implications have been limited. Equally the administration of proteins to cure disease has proved difficult. New smaller companies were launched and increasingly floated on the New York Stock Exchange. Disappointments here and elsewhere meant that stock market movements were particularly erratic. Thus the share price of Biogen, an early biotechnology enterprise and the first company to make interferon, was no greater in 1994 than a decade earlier, but in one quarter of 2000 had risen 2000%. See also **Köhler, Georges Jean Franz (1946–1995)** and **Milstein, Cesar (1927–2002)**; and **Monoclonal Antibodies**.

Stock market interest in companies had been spurred by the 1980 decision of the US Supreme Court to permit the patenting of a new organism. Eight years earlier the Exxon researcher Ananda Chakrabarty had applied for a patent to cover an organism that metabolized hydrocarbon waste. Although it did not use genetic modification, the organism's patent seemed to open the way to future patents for engineered organisms. This patent more than any other single event signaled the commercial potential of biotechnology to governments in other countries.

The early days of biotechnology were fired by hopes of medical products and high value pharmaceuticals. At the same time agricultural products were also being developed. Three early products which each raised substantial problems were bacteria that inhibited the formation of frost on the leaves of strawberry plants (ice-minus bacteria), genetically modified plants including tomatoes and rapeseed, and the hormone bST produced in genetically modified bacteria and administered to cattle to increase milk yields.

The first to come on stream were the ice-minus bacteria. These were fought through the courts in the US through the 1980s. Although they were approved after four years of controversy they have not to date been commercialized. Genetically modified (GM) plants followed. The first produce to enter the human food chain was chymosin, an enzyme used in the manufacture of cheese approved in 1990. The first whole food to be approved was the Flavr-Savr tomato declared to be safe in 1994. This contained antisense RNA, which expressed a protein slowing down

the softening process. The Foundation for Economic Trends, headed by Jeremy Rifkin, coined the word "Frankenfood" to challenge the concept of GM foods in 1993. In the event the Flavr-Savr was withdrawn from the market in 1997. However, Calgene, who had manufactured it, were taken over by Monsanto, a company that would pioneer a new range of plants that were resistant to their own herbicide "Round-up" (such as soybeans) or contained a gene from the bacillus *Bacillus thuringiensis* which attacked the corn-borer beetle (e.g., corn and cotton). By 1999 half the soybeans and one-third of the corn grown in the US was modified. Whereas the use of the ice-minus products had raised most anxiety in the US, the use of these products created anxiety first in Europe which then spread to the US.

Even more controversial than the use of GM foods was the medication of cattle using the GM-derived protein, bovine somatotropin. This had been extracted from the pancreas of cattle in the 1930s and shown to increase milk production. However, the cost was disproportionately large. The advent of GM technology meant that this protein could be expressed in modified bacteria and thereby manufactured cheaply. Milk production was greatly increased, at a certain cost, some claimed, to animal health. Socioeconomic consequences were foreseen since a reduction in milk price might make smaller production units uneconomic and small farms might go out of business. In Europe the use of bST has not been approved.

Such developments have been distinctively US phenomena, often associated with small companies spun-off from universities. The origins of the strong industrial–academic nexus in the US have been put down to entrepreneurial zeal. There has been a large literature on the proliferation of small companies. See also **Bioprocess Engineering (Biotechnology)**.

Human Genome Program

The sequencing of the human genome and its potential modification had been discussed from the 1960s. However, the scale of the task seemed gigantic. The development of automatic sequencers in the 1980s and the prospect of an international race focused attention in the United States. Following initiatives from the Department of Energy and from the National Institutes of Health (NIH), the US government formally launched its Human Genome Project in 1990. Plans were accelerated by the threat of competition from private companies and the US government agencies were joined by Britain's Wellcome Trust. When the first draft of the entire genome was announced in May 2000 almost 68,000 pages relating to the Human Genome Project were identified by the Google browser. See also **Human Genome Project (The)**.

However, even this might grow. The potential for public anxiety about the human future was revealed as early as 1997 with the first cloning of an adult animal, the sheep "Dolly" in Scotland. An intense debate emerged, much of it concerned not with the cloning of sheep which had been achieved but with the cloning of people which had not. A search with Google in July 2000 revealed almost 134,000 pages of material on the web in response to the words human and cloning, compared to 237,000 for cloning alone. See also **Cloning;** and **Cloning (The Story of Dolly the Sheep)**.

When the Human Genome Project was launched it was immediately obvious that it would raise ethical, legal and social issues. The identification of genes indicating proneness to diseases for which there was no cure, such as Huntington chorea, or diseases that were inherited and therefore risk factors for an entire family could be found by one member proving positive. The Human Genome Project therefore raised possibilities that had not been encountered before. Moreover, the problems of human engineering were once more on the agenda.

The problems it raised were therefore cultural as well as ethical and a large literature on the so-called "Yuk Factor" has explored the nature of the observable disgust that innovation has exhumed. Problems of patenting arose too. What could be patented when one is dealing with the building blocks of life? The 1986 US patent of an engineered mouse proved deeply troubling in Europe.

Biotechnology is thus deeply rooted in scientific and industrial tradition. It also raises questions that are at heart old. Yet the urgency with which at the beginning of the twenty-first century we have to make up our minds and the necessity of cultural change pushed by modern discovery, these are unprecedented. See also **Industrial Biotechnology**.

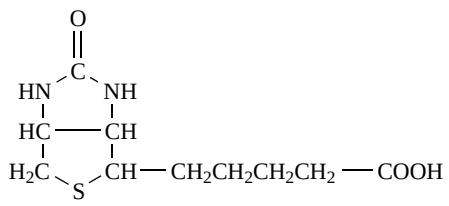
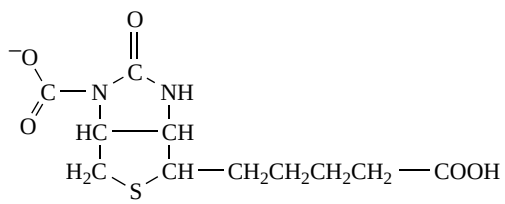
BIOTIC POTENTIAL. A quantitative expression of the dynamic significance of various inherent vital properties of living things, as a factor in the establishment of external relationships. It summarizes the reproductive and survival potentialities of the organism.

BIOTIN. [CAS: 59-30-3] Infrequently referred to as Bios IIB, protective factor X, vitamin H, egg white injury factor, and CoR. Biotin, required by most vertebrates, invertebrates, higher plants, and most fungi and bacteria, falls into the general classification of vitamins. In certain species, a deficiency of this substance is a cause of: desquamation of the skin; lassitude, somnolence, and muscle pain; hyperesthesia; seborrheic dermatitis; alopecia, spastic gait and kangaroo-like posture (rats and mice); dermatitis and perosis (chicks and turkeys); progressive paralysis, and K^+ deficiency (dogs); alopecia, spasticity of hind legs (pigs); and thinning and depigmentation of hair (monkeys).

Biotin reacts with an oxidized carbon fragment (denoted as CO_2) and an energy-rich compound, adenosine triphosphate (ATP), to form carboxy biotin, which is "activated carbon dioxide." Biotin is firmly bound to its enzyme protein by a peptide linkage. Biotin and carboxy biotin are:



Biotin



"Activated" carboxy-biotin

Biotin enzymes are believed to function primarily in reversible carboxylation-decarboxylation reactions. For example, a biotin enzyme mediates the carboxylation of propionic acid to methylmalonic acid, which

is subsequently converted to succinic acid, a citric acid cycle intermediate. A vitamin B_{12} coenzyme and coenzyme A are also essential to this overall reaction, again pointing out the interdependence of the B vitamin coenzymes. Another biotin enzyme-mediated reaction is the formation of malonyl-CoA by carboxylation of acetyl-CoA ("active acetate"). Malonyl-CoA is believed to be a key intermediate in fatty acid synthesis.

Bios, from the Greek, meaning life, was a word coined to describe a growth-promoting substance for yeast and discovered by Wildiers in 1901. When added in small amounts to sugar and salts medium, it permitted rapid growth of yeast even from a small seeding. Subsequent investigations proved that there was not merely a single substance involved, but that depending upon the strain of yeast and the circumstances of basting, a number of different substances could act, often synergistically, to promote the rapid growth of yeast. Pantothenic acid, biotin, inositol, thiamine, and pyridoxine all have "bios" properties when appropriately tested. Even an amino acid may be a limiting factor for yeast growth when other needs are supplied. The term "bios" has fallen from use in the literature.

Biotin required for growth and normal function by animals, yeast, and many bacteria is seldom found in deficiency in humans because the intestinal bacteria synthesize it in sufficient quantity to meet requirements. Biotin deficiency does occur, however, in animals fed raw whites of eggs. The egg white contains a protein, *avidin*, which combines with biotin, and this complex is not broken down by enzymes of the gastrointestinal tract. Hence, a deficiency develops.

Biotin was first isolated in pure form in 1936 by two Dutch chemists, Koegel and Tonnis, who obtained 1.1 milligrams from 250 kilograms of dried egg yolk. They showed that the compound was necessary for the growth of yeast and gave it the name, biotin. Five years later, in America, György and co-workers found that the same compound prevented the toxicity of raw egg white in animals and, in 1942, du Vigneaud and collaborators determined the structure of the compound.

Distribution and Sources. Natural sources of biotin include the following:

High biotin content (100–400 micrograms/100 grams)
Lamb liver, pork liver, soyal jelly, yeast
Medium biotin content (10–100 micrograms/100 grams)
Grains: Barley, corn (maize), oats, rice, wheat
Meat and Fish: Beef liver, chicken, eggs, mackerel, salmon, sardines
Nuts: Almonds, filberts, hazelnuts, groundnuts (peanuts), pecans, walnuts
Vegetables: Cauliflower, chick-peas, cowpeas, lentils, soybeans
Other: Chocolate, mushrooms
Low biotin content (0–10 micrograms/100 grams)
Dairy: Cheese, milk
Fruits: Apple, avocado, banana, cantaloupe, grape, grapefruit, orange, peach, strawberry, watermelon
Meat and Fish: Beef, halibut, lamb, oyster, pork, tuna, veal
Vegetables: Bean (lima), beet, beet greens, cabbage, carrot, lettuce, onion, pea, spinach, sweet corn, sweet potato, tomato

Biotin can be produced commercially by using, for starting the synthesis, meso-diamino succinic acid derivative of fumaric acid.

Determination of Biotin. Bioassay methods include the (1) rat and chick method (growth response after biotin deficiency); (2) microbiological with *L. arabinosus*. Physicochemical methods make use of polarography.

Bioavailability of Biotin. Factors which cause a decrease in bioavailability include: (1) presence of avidin in food; (2) cooking losses; (3) presence of antibiotics; (4) presence of sulfa drugs; and (5) binding in foods (such as yeast). Availability can be increased by stimulating synthesis by intestinal bacteria.

Antagonists of biotin include desthiobiotin in some forms, ureylene phenyl, homobiotin, urelenecyclohexyl butyric and valeric acid, norbiotin, avidin, lysolecithin, and biotin sulfone. Synergists include vitamins B_2, B_6, B_{12}, folic acid, pantothenic acid, somatotrophin (growth hormone), and testosterone.

Precursors for the biosynthesis of biotin include pimelic acid, cysteine, and carbamyl phosphate. Desthiobiotin acts as an intermediate. In plants, the production sites are seedlings and leaves. In most animals, production is in the intestine. Storage site is the liver.

Some of the unusual features of biotin noted by investigators include: (1) the binding and inactivation by avidin protein found in egg white; (2) fetal tissues and cancer tissues higher in biotin than normal adult tissues; (3) biotin deficiency increasing the severity and duration of some diseases, notably some of the protozoan infections; and (4) oleic acid and related compounds replacing biotin as unspecific stimulatory compounds in bacteria.

BIOTITE. A common silicate mineral containing potassium, magnesium, iron, and aluminum. Biotite is found in granitic rocks, gneisses, and schists. Although actually monoclinic, it often assumes a pseudohexagonal form. Like others of the mica group, it shows a highly perfect basal cleavage. Hardness, 2.5–3; sp gr, 2.7–3.4; luster, pearly to vitreous or sometimes sub-metallic when very black in color; cleavage sheets are elastic; color, greenish to brown or black; transparent to opaque. A general formula is $K(Mg,Fe)_3$, $(Al,Fe)Si_3O_{10}$ $(OH,F)_2$.

Biotite is occasionally found in large sheets, especially in pegmatite veins. It also occurs as a contact metamorphic mineral or the product of the alteration of hornblende, augite, wernerite, and similar minerals.

Biotite is found in the lavas of Vesuvius, at Monzoni, and in many other European localities; in the United States, especially in the pegmatites of New England, Virginia, and North Carolina, and the granite of Pikes Peak, Colorado. The mineral was named in honor of the French physicist, J.B. Biot. Biotite is also known as *iron mica*.

BIPEDALISM. Bipedalism is locomotion on two legs. Among living forms, birds and humans are exclusively bipedal.

The first vertebrates to conquer land had four limbs that were derived from the paired pectoral and pelvic fins of their aquatic ancestors. During terrestrial locomotion, such early tetrapods were quadrupedal, using coordinated action of fore- and hindlimbs (as well as undulations of the vertebral column) to support and propel the body. Over their subsequent 400+ million year radiation, most tetrapods retained quadrupedalism. However, some groups evolved bipedalism (bipedality).

Bipedalism has special significance to humans because we ourselves are bipedal. After infancy, we stand and move exclusively with our hindlimbs. Our hands and arms are poorly suited for terrestrial use because they are highly specialized for grasping. Among living forms, birds are also exclusively bipedal. The avian forelimb functions as a wing during flight, leaving the hindlimbs as the sole means of terrestrial movement. Because humans and birds are so specialized for bipedal locomotion, they can be considered "obligate" or habitual bipeds. Birds and humans differ in many ways, yet they share characteristics related to the common design constraints of obligate bipedalism.

Species that move on the ground using either four or two limbs are "facultative" bipeds. Like obligate bipedalism, facultative bipedalism has evolved independently multiple times within tetrapods. For example, many lizards are able to run on just their hind legs, but they stand and walk on all four limbs. Marsupials (e.g. kangaroos and wallabies) and several rodent groups (e.g. kangaroo rats and jerboas) have evolved bipedal hopping. Some nonhuman primates, bears and hoofed animals also have bipedal capabilities, but are still usually quadrupeds. As will be discussed, facultative bipedalism is a likely intermediate stage in the evolution from obligate quadrupedalism to obligate bipedalism.

Problems

Interesting questions regarding bipedalism include:

- How do bipeds stand or move?
- Is there more than one way a biped can move?
- How are different forms of bipedalism characterized?
- How did obligate bipedalism evolve in birds and humans?
- What anatomical and behavioral adaptations do bipeds typically evolve? and
- Why did bipedalism evolve?

Focus is on avian and human bipedal locomotion and the evolution of obligate bipedalism. A discussion of gaits and common adaptations is followed by an exploration of ideas about the origins and adaptive significance of bipedalism.

Gaits

Bipeds move their limbs in different ways. Some of these locomotor styles are considered distinct gaits, such as walking, running and hopping. A gait is often used over a specific range of speeds. Like shifting gears in a car, many animals change from walking to running at higher speeds. Similarly,

many facultative bipeds transition from four to two legs to achieve higher speeds. Compared to quadrupeds, however, bipeds are much more limited in their number of options. The individual movements of four legs can be combined into many more patterns and therefore gaits than the motions of two legs.

Gait Definitions. Understanding the definition and functional significance of each gait requires some basic terminology. Bipeds locomote using cyclical movements of the hindlimbs. One complete cycle is called a *stride*. Each limb spends a portion of a stride in contact with the ground. During this period, called the *stance phase*, the limb can support the body and change its forward speed. The stance phase is followed by the swing phase, during which the limb leaves the ground and is brought forward for the next stance phase.

Right and left limbs both undergo one stance phase and one swing phase per stride. However, their relative timing can vary, and interlimb coordination is one feature used to define different modes of bipedalism. In walking and running, for example, the right and left limbs are completely out of synchrony. When the right limb is in the middle of its stance phase, the left limb is in the middle of its swing phase. Such alternating limb timing is often referred to as "striding." In contrast, both limbs act in synchrony during hopping. The right and left limbs of hoppers have stance and swing phases that occur simultaneously, thereby effectively acting as one single limb. A third alternative is to avoid strict alternation or strict synchronization. Some birds move with some, but not complete, overlap of stance phases. Two different definitions of walking and running gaits are commonly used, based either on footfall patterns or on patterns of energetic fluctuation.

Swing Versus Stance Phase Duration. Walking is traditionally distinguished from running by the relative duration of the stance and swing phases of the stride (Fig. 1). In bipedal walking, each foot spends more than half of the stride in stance. Because the two feet are each on the ground more than half of the stride, there are times when both feet are on the ground simultaneously. Such overlapping of stance phases leads to "double support," which is characteristic of walking. In bipeds, running is traditionally defined as a striding gait lacking double support. During running, each foot spends less than half of the stride on the ground. As a result, there are times when both feet are off the ground simultaneously. Overlapping swing phases create an "aerial phase" as the body leaves the ground and follows a ballistic trajectory until the next stance phase. Hopping is quite similar to running in that it also has an aerial phase. Hoppers simply use both legs for every ground contact, whereas striding runners alternate stance phase legs between aerial phases.

Patterns of Energetic Fluctuations. More recently, walking and running have been distinguished by their underlying energetic mechanisms, rather than their footfall patterns (Fig. 1). Walking has been likened to an inverted pendulum, in which the body vaults up and over a relatively stiff stance phase leg. The body of a walking animal is highest at mid-stance, when the body's gravitational potential energy is at a maximum. The body then falls forward and down, converting gravitational potential energy into kinetic energy as the body increases its forward velocity. This increase in velocity is then used to drive the body upward on the next stance leg. Such an exchange between potential and kinetic energy saves some metabolic energy that would otherwise be used by muscles to elevate and accelerate the body with each step.

Running and hopping, in contrast, are bouncy, spring-like gaits. During ground contact, the stance phase limb of a runner is compressed like the spring in a pogo stick. In contrast to walking, a runner's body is lowest at mid-stance. As the limb compresses in the first half of stance, elastic strain energy is stored in its tendons and muscles. In the second half of stance, this energy is released as the stretched musculotendinous springs recoil, propelling the body upward and forward into the air. Kinetic and gravitational potential energy of the body are in phase, not out of phase as in walking. Like a bouncing rubber ball, a runner or hopper conserves metabolic energy by using its hindlimbs like springs, not like stiff struts as in walking. Birds running at intermediate speeds often lack an aerial phase (fitting the former definition of a walk), but are bouncing (fitting the latter definition of a run). This is one of several lines of evidence suggesting that this definition of walking and running is more accurate and meaningful than the previous, simpler definition, although both definitions often work well.

Comparison: Birds and Humans. Despite many differences in the musculoskeletal design of primate and avian hindlimbs, humans and birds share the energy-saving mechanisms of walking and running outlined above. Other similarities in anatomy and behavior are also present. For example, humans and birds all have highly adducted limbs, in which the feet are located below the body rather than out to the side as in more sprawling forms. Humans and birds also have relatively large ground contact surfaces. Birds walk on just their toes (digitigrady), but their three main digits tend to be relatively long and widely spread. Humans place their entire five-toed foot on the ground (plantigrady), thereby providing a large base of support. When differences in body size are accounted for, birds and humans use very similar combinations of stride duration and other parameters during locomotion. Such commonalities may be characteristic of obligate bipedalism in general, because they evolved independently in the separate lineages that gave rise to birds and humans.

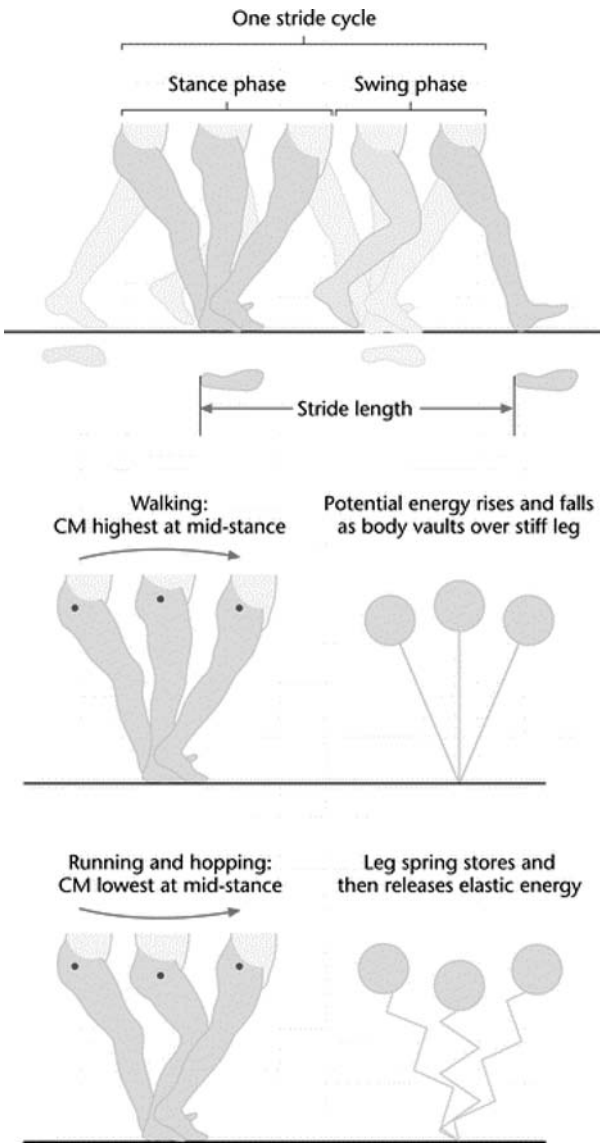


Fig. 1. Biomechanics of bipedalism. Top: elements of the stride cycle. Middle: inverted pendulum model of walking. Bottom: spring-like model of running. CM refers to the body's centre of mass.

Birds

In today's world, birds are easily recognized as feathered, flying, endothermic, beaked, bipedal vertebrates. Among living animals, birds are most closely related to the crocodylians (crocodiles, alligators, caimans, etc.). Crocodylians are all quadrupedal, and appear to offer little to the question of how, when and why birds became bipedal. However, birds and crocodylians are merely the surviving representatives of a much larger group of animals known as archosaurs, the "ruling reptiles." Archosaurs include many extinct forms, such as dinosaurs, that provide crucial evidence about the evolutionary history of obligate bipedalism in birds. See also **Aves (Birds)**.

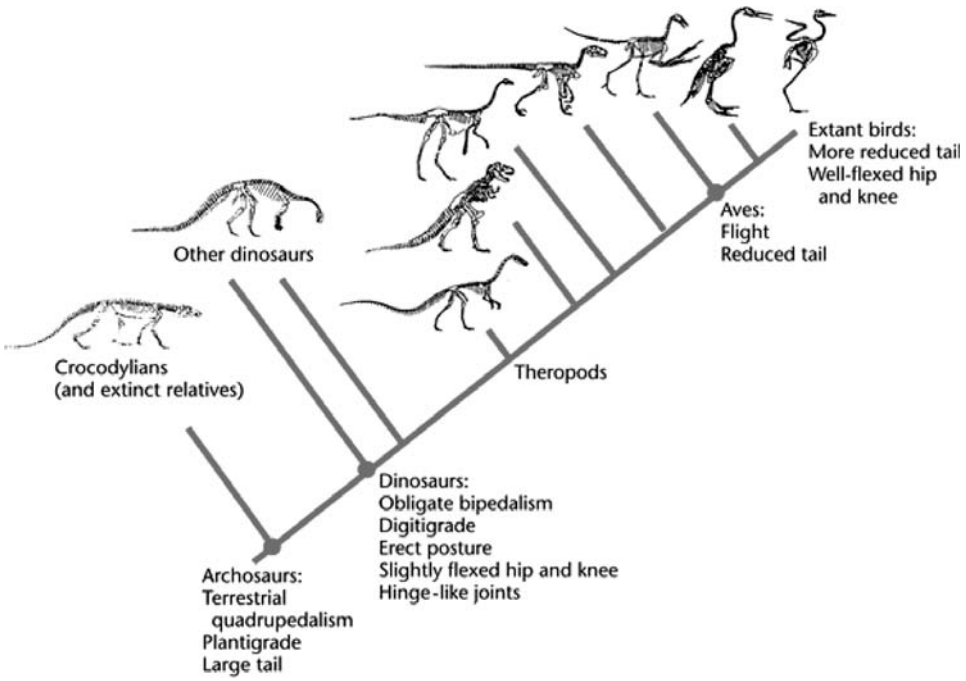

Fig. 2. Evolution of bipedalism in archosaurs. Key features are plotted on the phylogeny to reconstruct when they originated. Illustrated skeletons are modified from Carroll R.C. (1988) *Vertebrate Paleontology and Evolution*. New York: W.H. Freeman; following Gatesy 1990.

A phylogeny of archosaurs is required to trace the transformation from quadruped to biped on the line leading to extant (= modern, or living) birds. A phylogeny is a hypothesis of the evolutionary relationships between organisms, both living and extinct. By analyzing the distribution of morphological features, particularly those in the skeleton, evolutionary biologists can construct hypotheses of archosaur interrelationships and display them using phylogenies. Using such a phylogeny (Fig. 2), characteristics related to the evolution of bipedalism and locomotion can be surveyed in the clade Archosauria, allowing us to ask important questions. For example, when on the line to extant birds did bipedalism evolve? Is bipedalism a novelty seen only in birds, or did birds inherit bipedalism from their ancestors? Did bipedalism arise more than once in archosaurs? Do bipeds ever return to quadrupedalism?

Based on the phylogeny, the ancestor of all archosaurs was probably a medium-sized quadruped. Where do birds fit into the archosaur family tree? Numerous analyses have resolved that birds evolved from theropod dinosaur ancestors in the Mesozoic era, at least 150 million years ago. Theropods include carnivorous forms such as *Allosaurus*, *Tyrannosaurus* and *Velociraptor*, as well as their avian descendants. The ancestor of all dinosaurs, including the theropods, was probably a small obligate biped. Thus the striding bipedalism seen in living birds is at least 235 million years old. Obligate bipedalism may have evolved in other nondinosaurian archosaurs, although this is controversial. Early members of all dinosaur groups moved on two legs, but at least four lineages reverted back to quadrupedalism. Most armored dinosaurs, horned dinosaurs and long-necked sauropods were secondarily quadrupedal, having abandoned the bipedal abilities of their ancestors as their lineages attained larger body sizes. See also **Dinosaurs (Dinosauria)**.

Similarities Among Birds and Their Theropod Ancestors. Most importantly for this discussion, all theropod dinosaurs were striding, obligate bipeds. Evidence for bipedalism in theropod dinosaurs comes from the interpretation of skeletal remains, as well as from direct evidence of locomotor behavior: fossil footprints. Extinct theropods had long, digitigrade hindlimbs very similar to those of birds. Their forelimbs were typically much shorter, and bore predatory, grasping hands not suitable for locomotion on the ground. In forms with extreme forelimb reduction, such as *Tyrannosaurus*, habitual quadrupedalism was simply impossible. Additional evidence comes from the structure of the hindlimb joints: they are hingelike, mainly allowing only fore and aft motions (like the human knee), unlike the less constrained joints of crocodylians and other nondinosaurian reptiles.

Fossil trackways attributed to theropods confirm that all theropods were obligate bipeds, because impressions of the hands are almost never found. Left and right footprints alternate, indicating striding rather than hopping gaits. The prints are closely aligned as in other forms with highly adducted limbs. Indeed, the trackways of Mesozoic theropods differ little from those of birds today. Obligate bipedalism did not evolve with the origin of birds or the advent of flight. Rather, birds simply retained this locomotor style from their theropod ancestors.

Differences Between Birds and Their Theropod Ancestors. Despite strong similarities, extant birds differ from Mesozoic theropods in several important features, suggesting that their limbs were not functionally identical. One such difference is the tail. Birds are unusual in that they have lost the long, muscular tail characteristic of basal theropods. Such a tail allows the body to balance about the hips as a cantilever. Birds have reduced their tail, which is now mostly composed of feathers. To compensate, their limbs have reoriented to position the knee, rather than the hips, near the centre of mass. Consequently, birds use novel limb movements not present in earlier theropods. The crouched stance and horizontal trunk of birds is quite unlike humans, who have a more upright stance and vertical trunk. Maintaining this crouched stance requires more active muscle relative to the upright stance of humans. Several lines of evidence support the inference that early theropods had a more upright stance than birds do today.

A long tail also appears to have been important for the evolution of bipedalism in archosaurs. The heavy tail (as in crocodylians) locates the center of mass of the body posteriorly in comparison to a smaller tail (as in birds). The shift from quadrupedalism to locomotion on the hindlimbs is presumably easier if the hindlimbs normally carry a large portion of the body weight. Such a shift occurred in the lineage leading to dinosaurs, and possibly other archosaur groups. Controversy persists over the status of some archosaurs (such as the pterosaurs and ornithosuchids) as obligate striding bipeds, facultative bipeds, hoppers, or obligate quadrupeds. See also **Pterosaurs (Pterosauria)**.

Other changes in limb proportions, joint articulations, muscle attachments, body size and centre of mass position, and neural control of locomotion evolved along the line to extant birds. Thus the overall pattern of locomotion evolved from early bipedal dinosaurs to extant birds. Early theropods and other dinosaurs presumably moved unlike living birds in several ways, such as swinging the thigh (rather than the knee) through a large arc during walking.

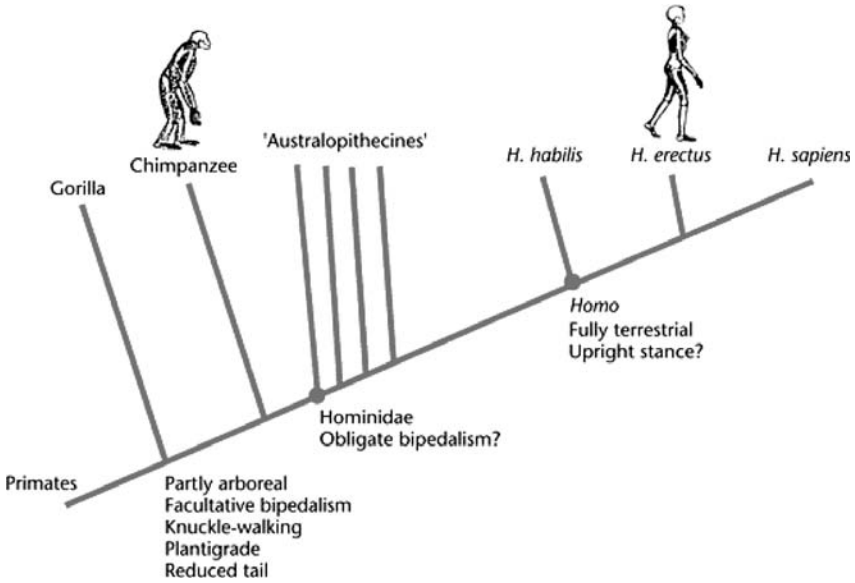

Fig. 3. Evolution of bipedalism in hominids. Key features are plotted on the phylogeny to reconstruct when they originated. It is unclear when the most derived features of human bipedalism evolved, but they were clearly present in *Homo erectus* and later hominids. Illustrated skeletons are modified from Norman D. (1994) *Prehistoric Life*. Macmillan, New York:

Humans

The history of human bipedalism is remarkably short by comparison with birds, but can be studied in much the same way. A phylogeny containing our close living and fossil relatives allows the evolution of bipedalism to be studied (Fig. 3). We (*Homo sapiens*) are members of the Hominidae, a group that also includes some extinct nonhuman primates (e.g. the species of *Australopithecus, Paranthropus* and *Ardipithecus*) and early humans (e.g. *Homo erectus*), but not gorillas or chimpanzees (the "great apes"). We are not the only obligate bipeds on the tree; we have several extinct relatives that probably were obligate bipeds. Thus obligate bipedalism is not unique to us; we inherited it from our ancestors. Like birds and other archosaurs, evidence for bipedalism in extinct hominids can be taken from fossil trackways as well as functional anatomy and the use of phylogenies.

Unfortunately, despite the quite recent acquisition of bipedalism by hominids, the exact point of origin of hominid bipedalism remains murkier than the origin of avian bipedalism. Lack of clear resolution of the interrelationships of hominids is a major obstacle that can be explained by the generally poor fossil record of hominids and their close relatives. Hundreds of fossils of the extinct relatives of birds are well known from complete skeletons (including feathers and other soft tissues), whereas comparatively few hominids are known even from partial skeletons. "Avian" (or dinosaurian) bipedalism has a 235+ million year, fossil-rich history compared to the known 3.5 million years of hominid bipedalism; it should not surprise us that many mysteries remain.

Evidence for Bipedalism in Human Ancestors. Some confident statements about the evolution of human bipedalism are possible. Facultative bipedalism and plantigrady are ancient features for apes and other primates, and hence were the ancestral conditions from which obligate bipedalism evolved. Most primates carry a disproportionate amount of their weight on their hindlimbs, which facilitates bipedalism. Bipedal hominids existed at least 3.5 million years ago, as shown by a number of bipedal, human-like fossil footprints at Laetoli, Tanzania. The identity of the track makers remains uncertain. Some think they were *Australopithecus afarensis*, bones of which are known from that area and time period (e.g. the famous "Lucy" skeleton). An unequivocal identification of the track maker would resolve the latest possible origin of bipedalism in Hominidae. Anatomical evidence for bipedalism includes modifications of the hip joint and limb muscles that balance the thigh in an upright stance and keep the trunk erect. For example, the ilium (upper bone of the pelvis) supports enlarged gluteal (posterior) muscles that are important for standing and running. Specialized knee and ankle joints place the foot underneath the hip joint. These features provide the ability to balance the body on one foot during upright standing and locomotion. The relatively straight leg minimizes the amount of active muscle needed to balance the body, acting much like a stiff column. The forelimb also lost some specializations for climbing, but gained manipulatory capabilities. Considering this evidence alone, it is clear that *Homo erectus* and other early humans from roughly two million years ago were obligate bipeds.

Like early theropods, early hominids probably moved in similar, but slightly different, ways compared to their living descendants. In contrast to the pattern of evolution in theropods, ancestral primates and perhaps some early hominids had a more crouched, less upright stance than their living descendants, who walk and run in an upright stance.

Controversies Regarding the Origin of Human Bipedalism. Debate has focused on the functional anatomy of the "australopithecines" (a diverse assemblage of nonhuman hominids). These hominids have more specializations for bipedalism than their nonhominid relatives do. Thus they had some, although probably not all, derived aspects of human bipedalism. It remains unresolved whether most australopithecines moved bipedally more like chimpanzees (with a crouched stance and shuffling motion) or more like humans (with an upright stance and smoothly striding motion). Some sort of intermediate form of locomotion is also plausible. Australopithecines probably spent less time in the trees than their nonhominid ancestors did, and spent more time on the ground. *Homo* did not evolve until almost 2 million years after the Laetoli hominid left its bipedal footprints. See also **Anthropoids**.

The origin of bipedalism predates most other major hominid innovations, such as tool use, a highly enlarged brain, larger body size, increased parental care, and more complex language and social organization. Thus bipedalism cannot be seen as a result of those innovations, but could be an important precursor to them. Beyond these statements, little consensus exists. More fossil discoveries will add resolution to this complex debate. The hominid lineage split off from the other apes around 5–7 million years ago. Yet the oldest known hominid, *Ardipithecus ramidus*, is only 4.4 million years old, indicating at least some undiscovered history.

Why Evolve Bipedalism?

Bipedalism is clearly an important part of the lives of birds and humans. Why it evolved is an exciting question with many ramifications. Yet it is a difficult question that may not even be indirectly testable. Teasing apart causation from mere correlation millions of years in the past is no simple task; multiple causes and strong (but noncausal) correlations might exist. Bipedalism is often cited as a "key innovation" that predisposed the avian and human lineages to achieve the success that they enjoy today (birds have around 10,000 species, whereas humans dominate the globe). Bipedalism is also often cited as a prerequisite for evolving other important adaptations, such as flight in birds or tool use in humans. Although these ideas may be interesting (albeit speculative), they focus on the events that

followed the origin of bipedalism. They have nothing to do with explaining why bipedalism evolved in the first place.

Explanations suggested for evolving bipedalism typically focus on the increased role of the forelimbs in nonlocomotor behaviors such as grasping and carrying food items (or tools). As corollaries, these explanations assume that the forelimbs became unimportant in locomotion as the hindlimbs became dominant. Of course, trade-offs exist; moving on two limbs rather than four may increase food manipulation ability, but decrease speed and/or stability. Other explanations for bipedalism that are falsified by the use of a phylogeny include arboreal climbing, leaping, gliding, or flight (in birds) or increased intelligence (in hominids). Because such traits evolved after obligate bipedalism evolved, they cannot be used to explain its origin.

Many other "just-so stories" such as social display have been advocated to explain the origins of bipedalism, but are the most difficult to test. Ultimately, the most compelling scenario is that avian and human bipedalism originated in conjunction with increased use of the forelimbs in some nonlocomotor behavior(s), although additional adaptive factors may have been quite important.

BIPHENYLS. Biphenyl consists of two benzene rings connected by a single bond. When subjected to chlorination, this anchor compound can be the source of over 200 different products. Known in the laboratory for many years, commercial production of polychlorinated biphenyls (PCBs) containing varying amounts of chlorine was commenced in the 1960s. PCBs are colorless liquids, with sp. gr. of 1.4 to 1.5. Important uses over the years have included heat-exchange and insulating fluids in closed systems, as transformer oils, hydraulic fluids, plasticizers, and carbonless copy paper. Consequently, with such a variety of uses, PCBs were distributed widely throughout the industrial countries. PCBs are persistent (i.e., they are not readily biodegradable).

Early in the 1970s, a number of PCB-contaminated food products were evidenced. River water contamination was noted in Michigan in 1973 and in the James River in 1975. In a somewhat later incident in Montana, a power transformer stored in a shed at a packing plant leaked PCB coolant into slaughterhouse sewage. The wastes were collected, rendered, and added to animal feed for distribution throughout nine states, with resultant damage to cattle. In 1979 a mass poisoning occurred in Taiwan from cooking oil contaminated by thermally degraded PCBs. In this instance, researchers in Taiwan and the U.S. studied the progeny of women who had been exposed to PCBs while pregnant. In 1985 117 children born to affected women and 108 born to unexposed women were examined and evaluated. The researchers reported in 1988, "The exposed children were shorter and lighter than those of the unexposed mothers. The children also had abnormalities of gingiva, skin, nails, teeth, and lungs more frequently than did the control group." There were deficits on formal developmental testing and abnormalities on behavioral assessment. Incidentally, the Taiwan outbreak occurred just after a similar, then mysterious, outbreak in Japan.

The foregoing incidents provided reasonable evidence of the connection between PCB contamination and the ingestion of food products. Regulatory agencies stepped in, and the commercial production of PCBs in the United States was halted in 1976.

PCB Problem Still Exists. Beginning when production was stopped and continuing well into the 1990s, millions of dollars were poured into research; disposal efforts continued because of the concern that untreated PCB wastes may be carcinogenic, and the effort continues amidst considerable dispute among: (1) those scientists who claim that PCB residuals are not carcinogenic and, therefore, very costly and drastic disposal operations are not justified, and (2) those researchers who believe that a head start on cleanup should be commenced, if only as a safeguard. Thus, there remain conflicting and changing signals from various regulatory agencies. In the late 1990s, the Environmental Protection Agency (U.S.) estimated that, during earlier years, over 450 million pounds (204 million kilograms) of PCBs had entered the U.S. environment. Considerable tonnage already has been treated, mainly by incineration procedures, but the greater masses of PCB residues remain to be treated. There has been some evidence of anaerobic dechlorination activity in river sediments, but, again, this is disputed by many experts. Also, of course, the entire question of whether PCB is carcinogenic remains essentially unproved. PCBs (60% chlorinated) have not been reported to be carcinogenic in animals, although PCBs with a lower chlorine content (54%) have not produced cancer in animals to a statistically significant extent.

This is the type of environmental problem that could continue for a decade or more without a universally accepted solution.

BIPOLAR COORDINATE. Choose two points $\pm a$ on the X-axis of a rectangular coordinate system. Then any point in the XY-plane could be measured in either of two polar coordinate systems where the poles are at $x = \pm a$; the polar axis in both systems is the X-axis; the two polar angles are θ_1, θ_2; the two radius vectors are r_1, r_2. Define the parameters $\xi = \theta_1 - \theta_2; \eta = \ln r_2/r_1$ and, in terms of these parameters,

$$x = \frac{a \sinh \eta}{\cosh\eta - \cos\xi}; y = \frac{a \sin \xi}{\cosh\eta - \cos\xi}$$

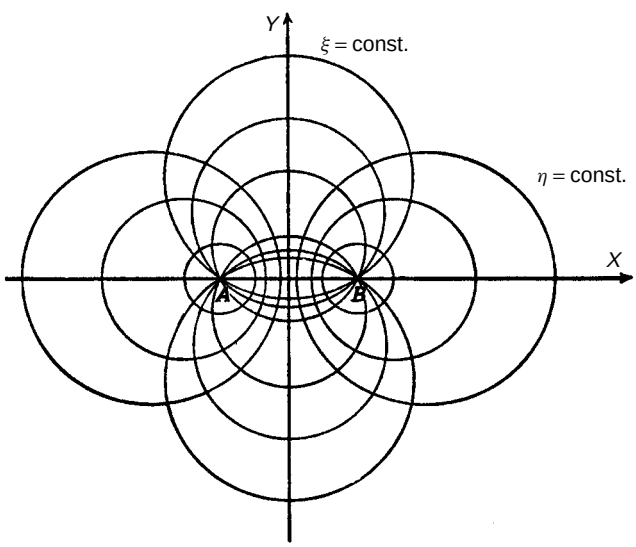

Fig. 1. Bipolar coordinate.

which are families of circles along the X- and Y-axes, respectively. Translation of these circles along the Z-axis produces the curvilinear coordinate system known as bipolar coordinates. See Fig. 1. They are families of right circular cylindrical surfaces with axes parallel to the Z-axis and centers at $y = 0$, $x = 0$, respectively ($\xi, \eta =$ constant), where

$$0 \leq \xi \leq 2\pi; -\infty \leq \eta \leq \infty$$

The third surface is a plane perpendicular to the Z-axis ($z =$ constant).

See also **Coordinate System**.

BIPOLAR ILLNESS. See **Manic-Depressive (Bipolar) Illness**.

BIPRISM. An optical prism with apex angle only slightly less than 180° used to produce a double virtual image of a point source. Interference fringes will appear on a screen placed before the biprism, as in the Young interference experiment. If the incident light is made parallel by a lens, placed between the source and the biprism, f is the apex angle of the biprism, ϕ is its refractive index, and b is the linear distance between consecutive fringes on the screen

$$\lambda = 2(n-1)b\phi$$

where λ is the wavelength of the incident light. The device may thus be used as a method for measuring the wavelength.

BIQUADRATIC EQUATION. An algebraic equation of the fourth degree in one or more variables, also called a quartic equation. If, as is usually the case, only one variable occurs, its general form is $a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4 = 0$. The transformation $x = y - a_1/4_0$ removes the term in x^3, so that the equation becomes $a_0y^4 + b_2y^2 + b_3y + b_4 = 0$. The standard form is $y^4 + py^2 + qy + r = 0$, where $p = b_2/a_0, q = b_3/a_0, r = b_4/a_0$.

The roots of this equation can be determined from an associated cubic equation, as first shown by L. Ferrari (1545). Consider $z^3 + c_1z^2 + c_2z + c_3 = 0$, where $c_1 = p/2; c_2 = (p^2 - 4r)/16; c_3 = -q^2/64$, called the cubic resolvent. Suppose its roots are $z_i = Y_i{}^2 i = 1, 2, 3$. Then the four roots of the biquadratic equations are $y_{1,2} = Y_1 \pm Y_2 \pm Y_3; y_{3,4} = -Y_1 \pm Y_2 \mp Y_3$. Either of the two possible values of Y_1 and Y_2, as found from $Y_i = \pm\sqrt{z_i}$, may be taken but Y_3 must satisfy the relation $Y_3 = -q/8Y_1Y_2$.

The nature of the roots can be predicted without obtaining them. In the following cases $D = 16p^4r - 4p^3q^2 - 128p^2r^3 + 144pq^2r + 256r^3 - 27q^4$ is called the discriminant.

(a) $q \neq 0$; p, q, r real; $z_1z_2z_3 = q^2/64 > 0$.

1. z_1, z_2, z_3 all positive; four real roots; $D \geq 0$; $p < 0, (q^2 - 4r) > 0$; no more than two roots are equal.

2. z_1 positive; z_2, z_3 negative; two pairs of conjugate imaginary roots; $D < 0$.

3. z_1; positive; z_2 and z_3 conjugate imaginary; y_1 and y_2 real; y_3 and y_4 conjugate imaginary.

(b) $q = 0$. The cubic resolvent has one zero root, therefore the biquadratic has two pairs of equal roots, but with opposite signs.

Application of these equations to calculate the roots of a biquadratic equation would be extremely laborious and anyone would be ill-advised to use them for this purpose. Approximate methods, as in the case of the cubic equation, are much more satisfactory. See **Approximate Calculation**.

BI-QUARTZ. By placing two adjoining pieces of equal thickness of quartz, one dextro-, the other laevo-rotatory, over the analyzer in a polariscope, the accuracy of setting can be increased. Such a double block is called a bi-quartz. See also **Polarized Light**.

BIRAMOUS APPENDAGE. The primitive jointed appendage of the arthropods, still found in various form in the crustaceans.

The appendage consists of a single basal portion called the protopodite, which is usually divided into a proximal coxopodite and a distal basipodite. It may bear on its outer margin one or several lobes called epipodites. From the protopodite two branches arise, an inner endopodite and an outer exopodite; this characteristic of the appendage is responsible for the name biramous. The endopodite is divided into five or fewer segments, named in order from the base the ischiopodite, meropodite, carpopodite, propodite, and dactylopodite. The exopodite is much less uniform and is often lacking.

These appendages have become modified and specialized for many functions in the existing crustaceans, as is nicely demonstrated by the appendages of the crayfish and lobster. In these animals they form sensory organs (antennae), mouth parts (jaws and accessory appendages), walking legs, swimmerets, accessory reproductive organs, and broad, flat swimming appendages. They are also regarded as the form from which the simpler jointed appendages of insects and other arthropods have been evolved.

BIRCH TREES. Members of the family Betulaceae (birch family), these trees are of several species. These are deciduous shrubs or trees known for their ornamental bark. They are hardy and grow fast, particularly when young. Important species of the birch family include:

Black or river birch	*Betula nigra*
Canoe birch	*B. papyrifera*
Cherry birch	*B. lenta*
Chinese paper birch	*B. albo-sinensis*
Common birch	*B. pubescens*
Forrest's birch	*B. forrestii*
Gray birch	*B. populifolia*
Himalayan birch	*B. jaquemontii*
Japanese silver birch	*B. platyphylla japonica*
Monarch birch	*B. maximowicziana*
Poplar-leaved birch	*B. populifolia*
Russian rock birch	*B. ermanii*
Silver birch	*B. pendula*
Southern white chinese birch	*B. albo-sinensis septentrionalis*
Swedish birch	*B. pendula "Dalecarlica"*
Yellow birch	*B. lutea*

Various species of birch trees are found in Europe, northeastern Asia, and North America, particularly northern and eastern, but with some varieties extending westward and into Alaska. Some species were introduced into North America from Europe. Birches tend to be quite slender, the trunk diameter of some 50-year-old trees not exceeding 15 inches (38 centimeters). However, the trees tend to be more stout where they are found in warmer areas. The flower of both sexes is found on the same tree. It is spike-like with clusters close to the branch. There are no petals; the catkins mature in early spring. The fruit is a hard nut in the catkins.

The paper birch (also known as white birch or canoe birch) is possibly the best known of the birches in North America. It is a superior tree among the various species. The tree is well known for its flexible, smooth and white bark, which is probably best known for its use by American Indians in the construction of canoes. The paper birch normally ranges up to 70 feet (21 meters) in height, but as shown by the accompanying table, can reach close to 100 feet (30 meters) in height. The leaves are a dark green, pointed, ovate, and coarsely toothed. The tree ranges westward from Newfoundland to Hudson Bay (southern portion) and to the Alaskan coast. In the west, it is found as far south as Washington and Montana. In the eastern states, it is found commonly in New England and northern New York State, and ranging down into Connecticut. The pale-brown, close-grained wood finds use as pulp wood and for making numerous small items such as spools and shoe lasts — some of these uses having been replaced by plastics and other materials in recent years. In the green state, paper birch has a moisture content of 65% and weighs 50 pounds per cubic foot (801 kilograms per cubic meter). When air dried to 12%, the weight is 44 pounds per cubic foot (705 kilograms per cubic meter) and 1000 board feet (2.36 cubic meter) of nominal sizes weigh 3160 pounds (1433 kilograms). The crushing strength of the green wood with compression applied parallel to the grain is 2360 per square inch (16.3 MPa); 5690 psi (39.3 MPa) for the dried wood. The tensile strength of the green wood with tension applied perpendicular to the grain is 380 psi (2.6 MPa).

The sweet birch (or black birch or cherry birch) is found in midwestern Canada and the United States eastward to the Atlantic. It is found in the Allegheny Mountains, extending southward into Kentucky, Tennessee, and even in parts of western Florida. The tree is dense with foliage, having a rounded top. The bark is cherry in color. The wood is heavy and strong. At one time, the wood was extensively used in Nova Scotia and New Brunswick by the shipbuilding industry.

The gray birch (*B. populifolia*) is common in the United States. The bark is white, spotted with dark scars. The tree tends to grow in clumps.

TABLE 1. RECORD BIRCH TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Alaska Paper birch (1993) (*Betula papyrifera var. neoalaskana*)	72	183	64	19.5	21	6.4	Alaska
Alaska Paper birch (1993) (*Betula papyrifera var. neoalaskana*)	56	142	74	22.6	33	10.1	Alaska
Gray birch (1999) (*Betula populifolia*)	41	104	57	17.4	50	15.2	Wisconsin
Kenai birch (1994) (*Betula papyrifera var. kenoica*)	50	127	47	14.3	19	5.79	Alaska
Mountain Paper birch (1995) (*Betula papyrifera var. cordifolia*)	112	284	67	20.4	80	24.4	Michigan
Northwestern Paper birch (1999) (*Betula papyrifera var. subcordata*)	46	117	65	19.8	32	9.75	Idaho
Paper birch (typ.) (1991) (*Betula papyrifera var. papyrifera*)	220	559	107	32.6	76	23.2	Michigan
Paper birch (typ.) (1996) (*Betula papyrifera var. papyrifera*)	222	564	107	32.6	76	23.2	Michigan
River birch (1999) (*Betula nigra*)	188	478	90	27.4	100	30.5	Tennessee
Sweet birch (1989) (*Betula lenta*)	182	462	78	23.8	80	24.4	New Hampshire
Western Paper birch (1989) (*Betula papyrifera var. commutata*)	189	480	81	24.7	57	17.4	Washington

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

In burned-out areas, the gray birch is often the first tree to be seen making a start out of the charred ground. The tree, also known as the white birch, Oldfield birch, or poplar birch, is relatively small (20–30 feet in height; 6 to 9 meters) with a slender trunk (from 6 to 10 inches in diameter; 15 to 25 centimeters). The tree frequently is found in what might be termed wasteland — swampy areas, rocky slopes and pastures. It is found throughout New England and northern New York and up into the region of the lower St. Lawrence. The tree has a preference for coastal areas — along the Atlantic, eastern Great Lakes, and rivers. The wood finds limited commercial use.

The river birch (*B. nigra*) is native to the eastern United States. The tree is pyramidal in shape, with a reddish-brown bark. It is frequently found near water or streams and has a shallow root system. Probably the most abundant of the birches in the United States is the yellow birch (*B. alleghaniensis*), found from Newfoundland to the Gulf Coast. The wood is of a deeper brown color than most other species of birch. The wood is strong, hard, tough, close-grained, and can be polished to appear like cherry or mahogany. The wood is used for furniture, handles, trim, and paneling. The green wood has a moisture content of 62% and weighs 57 pounds per cubic foot (913 kilograms per cubic meter). When air-dried to 12% moisture content, the weight is 44 pounds per cubic foot (705 kilograms per cubic meter) and 1000 board feet (2.36 cubic meters) of nominal sizes weigh 3670 pounds (1665 kilograms). The crushing strength of the green wood with compression applied parallel to the grain is 3510 psi (24 MPa); of the dried wood, 8310 psi (57 MPa). The tensile strength with tension applied perpendicular to the green is 430 psi (3 MPa) for the green wood; 930 psi (6.4 MPa) for the dried wood.

Some of the species just described, notably the gray and river birches, are short lived.

The common birches of Europe include the *B. pendula*, capable of attaining a height of 75 feet (22.5 meters) and having a white bark; and the *B. pubescens*, the common white birch (or downy birch) of both Europe and northern Asia. The latter tree has a white, peeling bark, but is not quite as showy as its American counterpart. The tree can attain a height of about 65 feet (19.5 meters). Various species of birches also are found in Japan, Manchuria, the region of the Himalayas, and China. Generally, the birches prefer the northern climates. See Table 1.

BIRD BURST. Radar echoes caused by flocks of roosting birds that take to the air as a group and fly away in different directions. Bird bursts typically occur near sunrise and have ring-shaped reflectivity signatures with weak echoes in the center and maximum reflectivity in circles that expand with time around the roosting site. In Doppler radar observations, the velocity signature resembles that of a microburst at low levels.

BIRD LOUSE *(Insecta, Mallophaga).* A wingless ectoparasitic insect with biting mouth parts. Most species of bird lice live among the feathers of birds and eat bits of feather and other debris. Although a few species are found on mammals, the prevailing type of host has given its name to the entire order; the name biting lice is also distinctive.

The bird lice that affect poultry are economically important. Even though they do not suck blood like other parasites, the irritation resulting from their presence in large numbers is serious to the birds. Various measures of control have been devised, among them white-washing roosts, oiling perches with kerosene, and the use of various insect powders in nests and on the birds themselves. The maintenance of clean surroundings for the flock is of the utmost importance in preventing severe infestation.

BIRD OF PARADISE *(Aves, Passeriformes).* Any of the numerous and beautiful species that make up the family *Paradisaeidae*. They are characterized by the gorgeous colors, remarkable displays, and bizarre forms of the plumage and are unsurpassed in splendor by any group of birds, although they are fairly near to the crows in classification. Most of the about 40 species are found in New Guinea.

The tail of the bird of paradise may be as much as 3 feet (0.9 meter) long. The plumage is fine and silky, with black and purple or grackle-like coloration. Only the males have the highly colored plumage. The female is dull and drab. These birds make a variety of noises, ranging from a weak "peep" to throaty "caws," trumpetings, snaps, and hisses. See illustration.

Although the male carves out a single territory that he defends vigorously, he is promiscuous. There is no bond or pairing off before mating as in the instances of many birds. The female builds her own nest and feeds the young. The nest is shallow, cup-like, and found in vines — only occasionally in trees. The egg-shells are irregularly streaked.

When the bird of paradise was first discovered in New Guinea (about 1522), much trading in the plumes developed. At the peak of demand by Europeans, more than 50,000 skins were sold annually. Today, this trade and practice are forbidden.

An excellent description of the bird of paradise is given by B.M. Beehler in "The Birds of Paradise," *Sci. Amer.*, 116 (December 1989). See Fig. 1.

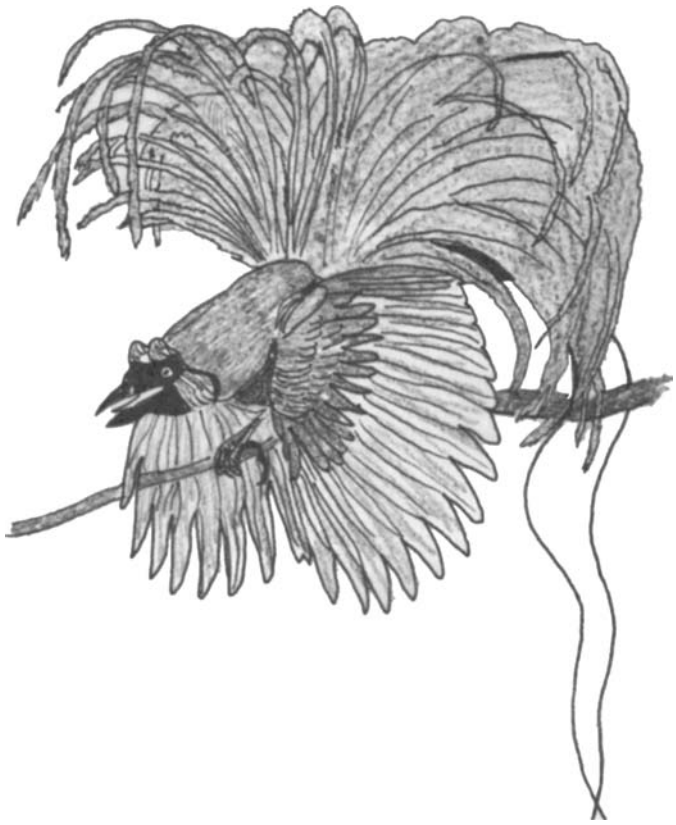

Fig. 1. Red bird of paradise (*Paradisaera rubra*). (*Sketch by Glenn D. Considine*.)

BIRDS. Of the phylum *Chordata*, subphylum *Vertebrata*, and class *Aves*, birds, related ancestrally to the reptiles, which is apparent from reptilian scales on their legs, have numerous distinctions, most notable of which is the ability to fly, and part and parcel of which is possession of feathers, a unique anatomical feature not found in any other animal. See **Fossil Birds**.

Classification of Birds

As indicated by Fig. 1, there is a tremendous variety of form, size, and habit among the 28 orders of birds. Conventionally, the birds are put into 27 orders, although some authorities put flamingos into a separate order. A listing of the orders and parenthetical definition of the content of each order is given in the footnote to Table 2. Within these orders of birds, there are over 150 families with a total of something less than 9000 species. It should also be noted that a few authorities stretch the list of orders to 29 by separating the touracos from the cuckoos. Nearly 130 of the more important or interesting species of birds are described in this volume. Table 1 lists the specific entries providing topical coverage in this volume. It is not uncommon to have the Latin family name of a particular species as the starting information. When this is the case, Table 2 provides a convenient means for going from the Latin family name to the English family name, with examples — as well as providing information on the common name of a species. The Latin family name, very helpful in literature searching, may be found in Table 3, along with the family names and orders for over 400 species of birds.

Bird Anatomy and Physiology

The external structural features of a "typical" bird are shown in Fig. 2 on p. 470. Highlights of bird anatomy and physiology include: (1) the skin is covered with feathers; (2) the jaws are sheathed in a horny beak, and bear no teeth; (3) the pectoral appendages are usually modified for flight, forming wings (although they are rudimentary in some species and aid in swimming in others); (4) the skeleton is made rigid by the fusion of bones; (5) the heart is four-chambered; and (6) the birds are warm-blooded, with a blood temperature ranging from 102 °F to as high as 112 °F (39 °C to 44.5 °C).

As is true of all extensive groups, the birds are very diverse in habits. They are both herbivorous and carnivorous, and are further distinguished as seed-eaters, fruit-eaters, insect-eaters, fish-eaters, and other types. In addition to their usual ability in the air, they are also distinguished as swimmers, waders, walkers, runners, divers, and, in a few cases, burrowers. Their nesting habits vary remarkably and the construction of the nest is, in many cases, a source of wonder.

In anatomy, the skeleton of a bird is frequently compared with that of a reptile, the main differences being made necessary by the two differing modes of locomotion. Bipedal locomotion of the bird requires modification of the hind limbs and pelvic girdle. For flight, the pectoral girdle and forelimbs are modified. The trunk is rigid and the sternum is characterized by a median ridge called the keel. Extending rearward from selected ribs are short projections (*uncinate processes*) which contribute to firming up the thoracic framework. The bones of birds are made very light by virtue of numerous air cavities. The skull, in particular, is very lightweight. The orbits are quite large. By extension of the facial bones, a bill is formed. There are no teeth.

In birds, the muscles, particularly of the wings, neck, tail, and legs, are extremely well developed. The *pectoralis major*, the muscle that causes the downward stroke of the wing, often will weigh as much as 20% of the total weight of the bird. The muscle that raises the wing is called the *pectoralis minor*. Together, these muscles comprise what generally is called the breast of the birds. Birds have a unique muscular mechanism that takes over when a bird assumes a squatting position for rest or sleep. In this position, certain tendons are pulled and these, in turn, flex the toes, essentially locking the bird to its perch.

Beaks of birds show a wide range of specialization, especially as related to different types of diet. Slender and elongate beaks are found in many wading species, which must reach below the surface of water for food.

Hummingbirds require sword-like beaks to obtain nourishment from deep-throated flowers. The broad beak of the duck has sieve-like structures at the sides and serves effectively to collect and strain out small particles from the water. The hooked beaks of birds of prey, the small and slender beaks of insectivorous birds, and the thick, strong beaks of seed-eating species, such as the parrots, indicate the wide range. See Fig. 3 on p. 470.

Birds are known for their high rate of metabolism. Large quantities of food are needed and digestion must be rapid. Relative to other organs of the body, the bird's heart is large. The heart may beat several hundred times per minute in a perching bird and up to a thousand times or more per minute in a canary when it is under stress.

Inspection of the wings of a bird reveals much concerning the habits and frequently the habitat of a given species. Long, narrow wings, for example, are found in the shearwaters and other ocean gliders. A shorter, more stubby wing is found in the species, such as pheasants, that require a lot of power for getting off the ground quickly. Broad, slotted wings are found among the soaring birds, such as hawks. Short, light, but strong wings are found on those birds such as swallows, which require high speed and great efficiency for long migratory flights. Wing design greatly affects the bird's gliding ability — extremely accentuated in the albatross, considerably less in the pigeon, a lot less in the sparrow, and very limited in the hummingbird. On the other hand, the hummingbird has wings that can swivel nearly 180° at the shoulder to provide just the right combination of lift and thrust during its wing movements to permit it to literally hang in the air in its hovering mode. Birds such as the albatross take full advantage of dynamic soaring, utilizing thermal air currents and the particular wind action next to the surface of ocean waves to maintain a gliding pattern with little flapping effort for many hours over the ocean.

Probably because specialization for flight overshadows other adaptations, the classification of birds has been subject to some difficulty. The birds are divided into two subclasses by some writers, the *Ratitae* including flightless birds whose sternum is without the deep keel to which the powerful flight muscles are attached, and the *Carinarae* with a keeled sternum. These divisions are not, however, clean cut.

The development of a feather indicates that it is a modified scale, like those of reptiles. A feather consists of a central axis or rachis continuous with the hollow quill that is attached to the body. The rachis bears the flat vane of the feather, which is made up of many slender barbs bearing barbules along each side. The barbules of adjacent barbs interlock to form the continuous surface of flight feathers and the similar contour feathers of the body. Down feathers are of generally soft structure and lack barbules, and filoplumes are slender feathers with few barbs. The three types of feathers

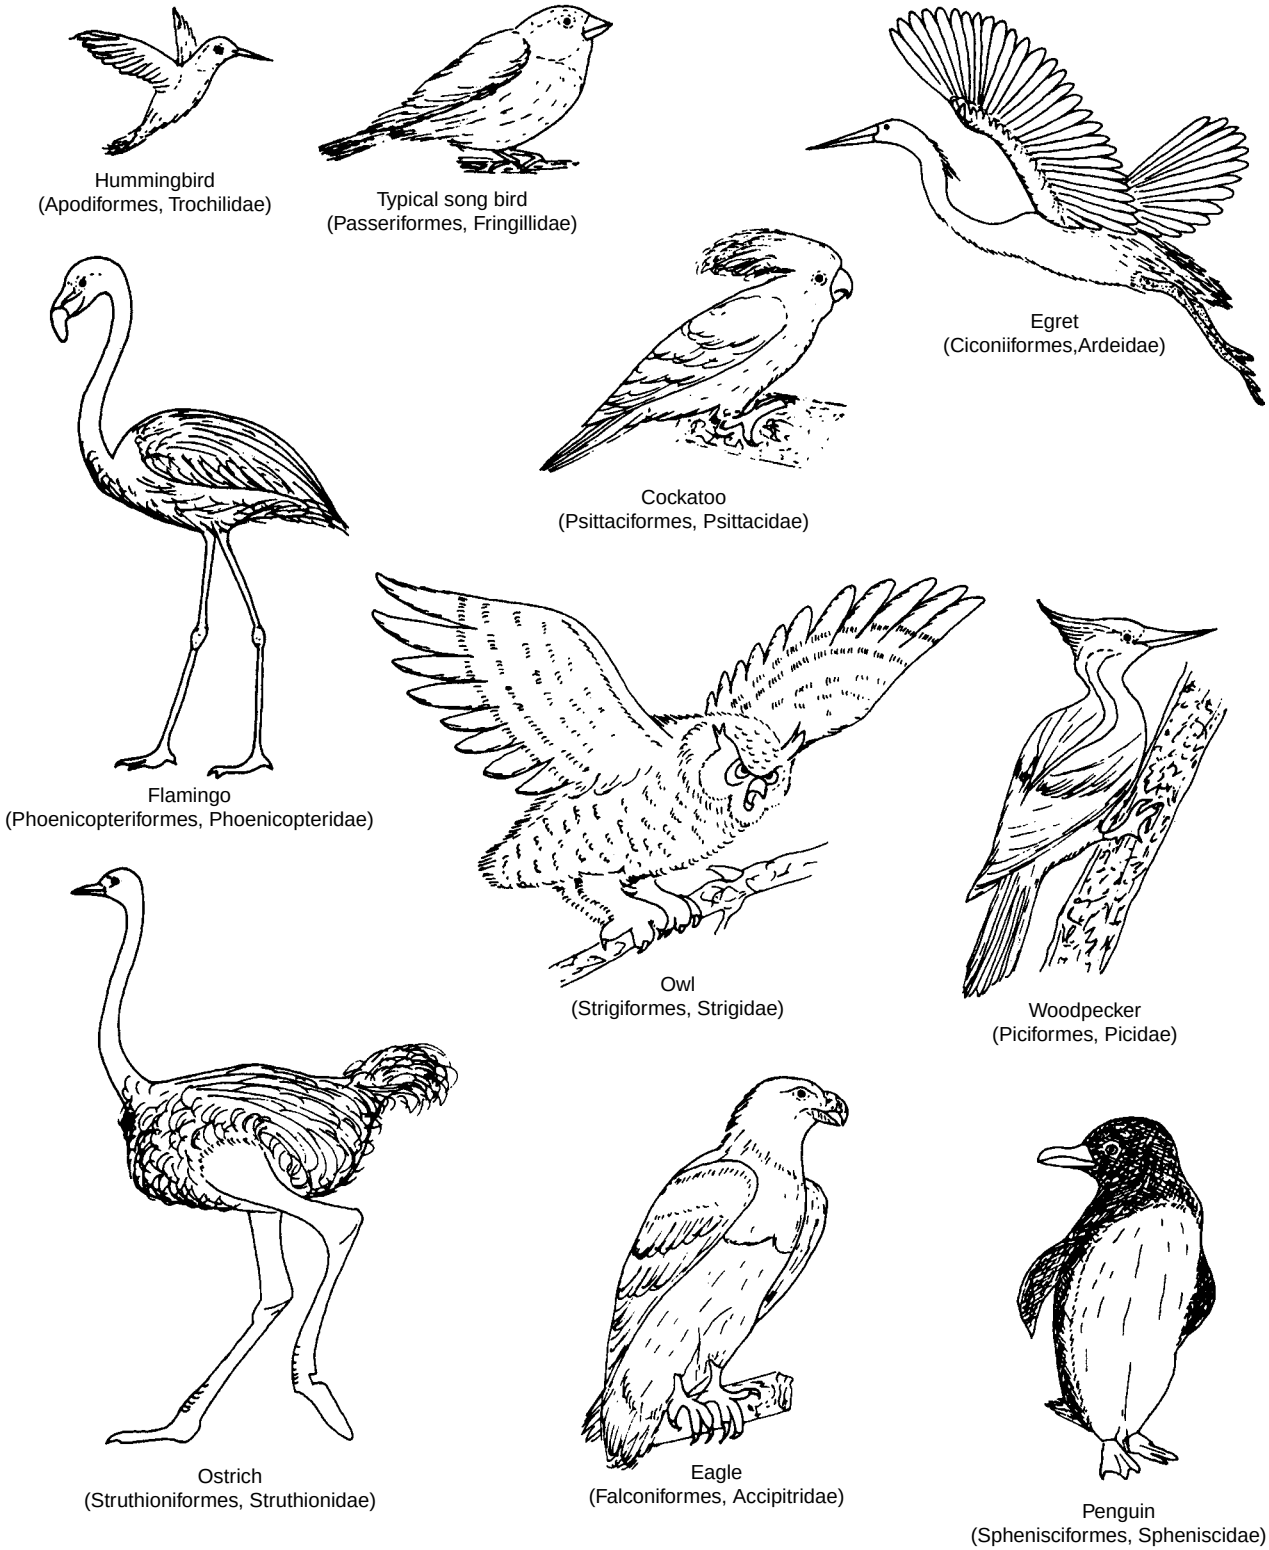

Fig. 1. Very abridged representation of various bird forms.

are shown in Fig. 4 on p. 470. When birds shed their feathers, they are said to *molt.* This usually happens in late summer, at which time the bird develops a new set of feathers. These are formed within the same follicles and are from the same papillae from which the old feathers were cast away. In some species, there is another, often partial, molt just at the start of the breeding season. Often fresh coloration is shown at this time.

Migratory Habits

The seasonal migrations of birds are almost unique. No other group of animals is so generally characterized by this tendency. The subject has been widely studied and has aroused much speculation without being clearly understood. It is obviously correlated with seasonal variation in the food supply and with climatic conditions, and is made possible by high specialization for flight, but exact knowledge of cause and effect in migration is lacking.

Notable among the migratory birds is the Arctic tern, which makes a round trip each year (about 10,000 miles in each direction; 16,090 kilometers) between the Arctic and Antarctic. The white stork is also a well-known migrator, summering in Europe and wintering in South Africa. They do not like flying over water and thus select a route to the east of the Mediterranean, or make the crossing at Gibraltar. Breeding in North America, the bobolink winters in Argentina. The route includes short hops

TABLE 1. TOPICAL COVERAGE OF BIRDS IN THIS VOLUME

Order of Birds	Title of Entry
ANSERIFORMES (Duck, goose, swan)	Anseriformes
	Waterfowl
APODIFORMES	Apodiformes
	Swifts and Hummingbirds
APTERYCIFORMES	Kiwi
CAPRIMULGIFORMES (Frogmouth, goatsucker, nightjar, Nighthawk, oilbird, potoo)	Caprimulgiformes
	Nightjars and Nighthawks
CASUARIIFORMES	Cassowaries
	Emu
CHARADRIIFORMES (Auk, gull, plover, puffin, tern)	Charadriiformes
	Waders, Shorebirds, and Gulls
CICONIIFORMES	Bittern
	Ciconiiformes
	Heron
	Ibis
	Screamer
	Stork
COLIIFORMES	Coliiformes
	Mousebird
COLUMBIFORMES	Columbiformes
	Pigeons and Doves
CORACIIFORMES (Bee-eater, hoopoe, hornbill, Kingfisher, motmot, roller, tody)	Coraciiformes
	Kingfishers and other Coraciiformes
CUCULIFORMES	Cuckoos and Coucals
	Cuculiformes
	Turacos
FALCONIFORMES	Caracara
	Condor
	Eagle
	Falcon
	Falconiformes
	Hawk
	Vulture
GALLIFORMES	Curassow
	Galliformes
	Grouse
	Hoatzins
	Jungle Fowl
	Maleo
	Megapode
	Mound Birds
	Partridge
	Peafowl
	Pheasant
	Ptarmigan
	Quail
	Tragopans
	Turkey
GAVIIFORMES	Gaviiformes
	Loon
GRUIFORMES	Gruiformes
	Rails, Coots, and Cranes
PASSERIFORMES (Perching and song birds)	Bird of Paradise
	Blackbird
	Bluebird
	Bluethroat
	Bobolink
	Bowerbird
	Broadbills
	Bulbul
	Bullfinch
	Bunting
	Canary
	Cardinal
	Chatterer
	Chickadee
	Cowbird
	Creeper
	Crow
	Finch
	Fringillidae
	Gnatcatcher
	Grackle
	Jay
	Junco
	Kingbird
	Lark
	Lyrebird
	Magpie
	Manakin
	Martin
	Meadowlark
	Myna
	Nightingale
	Nuthatch
	Oriole
	Ouzel
	Passeriformes
	Raven
	Redstart
	Robin
	Shrike
Other species are covered under entry on **Passeriformes**.	Sparrow
	Starling
	Swallow
	Tanger
	Thrasher
	Thrush
	Tit
	Warbler
	Waswing
	Weaverbird
	Wren
PELECANIFORMES	Pelecaniformes
	Pelicans and Cormorants
PHOENICOPTERIFORMES	Flamingo
	Phoenicopteri
PICIFORMES	Piciformes
	Woodpeckers and Toucans
PODICEPEDIFORMES	Grebe
	Podicepediformes
PROCELLARIIFORMES	Petrels and Albatrosses
	Procellariiformes
PSITTACIFORMES (Cockatoo, kaka, kea, lory, love-bird, macaw, parakeet, parrot)	Parrots and Cockatoos
	Psittaciformes
RHEIFORMES	Rhea
SPHENISCIFORMES	Penguin
	Sphenisciformes
STRIGIFORMES	Owls
	Strigiformes
STRUTHIONIFORMES	Ostrich
	Ratites
TINAMIFORMES	Tinamiformes
	Tinamous
TROGONIFORMES	Trogon
FOSSIL BIRDS (Archaeopteryx, Ichthyornis)	Fossil Birds
POULTRY	Poultry

between the islands of the Caribbean. The pectoral sandpiper prefers to breed in the tundra of the Arctic, but winters in South America, crossing mid-North America in each direction. While commonly regarded as an escape to warmer climate, the predominant motivation behind migration is that of an assured food supply during all seasons of the year. Studies indicate that migratory flights generally occur at altitudes of 3000 feet (900 meters) or less, particularly migrations involving large flocks. Single migrating birds may travel at much higher altitudes, going as high as 14,000 feet (4270 meters). There have been some radar sightings of birds at elevations up to 20,000 feet (6100 meters).

TABLE 2. ALPHABETICAL LIST OF FAMILY BIRD NAMES-LATIN TO ENGLISH (Number in ( ) after Latin name indicates Order of which Family is a part.)

Latin Family Name	English Name or Examples
Accipitridae (13)	Eagle, hawk, Old World vulture, harrier
Aegothelidae (21)	Owlet nightjar
Alaudidae (27)	Lark
Alcedinidae (25)	Kingfisher
Alcidae (16)	Auk, murre, guillemot, dovekie, puffin
Anatidae (12)	Goose, swan, duck
Anhimidae (12)	Screamer
Anhingidae (10)	Snakebird, anhinga
Apodidae (22)	Swift
Apterygidae (4)	Kiwi
Aramidae (15)	Limpkin
Ardeidae (11)	Heron, bittern, egret
Artamidae (27)	Scrub-bird
Atrichornithidae (27)	Scrub-bird
Balaenicipitidae (11)	Whale-headed stork
Bombycillidae (27)	Waxwing, silky flycatcher, hypocolius
Brachypteraciidae (25)	Ground roller
Bucconidae (26)	Puffbird
Bucerotidae (25)	Hornbill
Burhinidae (16)	Thick-knee, stone curlew
Callaeidae (27)	Wattled crow, huias, saddleback
Campephagidae (27)	Cuckoo-shrike, minivet
Capitonidae (26)	Barbet
Caprimulgidae (21)	Goatsucker, nightjar, whip-poor-will
Carduelinae (27)	Crossbill, northern grosbeak, siskin, canary
Cariamidae (15)	Cariama, seriema
Casuariidae (3)	Cassowary
Catamblyrhynchidae (27)	Plush-capped finch
Cathartidae (13)	New World vulture
Certhiidae (27)	Creeper
Chamaeidae (27)	Wren-tit
Charadriidae (16)	Plover, turnstone, surf bird
Chionididae (16)	Sheath-bill
Ciconiidae (11)	Stork, jabiru
Cinclidae (27)	Dipper or water ouzel
Cochleariinae (11)	Boat-billed heron
Coliidae (23)	Mousebird, coly
Columbidae (17)	Pigeon, dove
Conopophagidae (27)	Ant-pipit, gnat-eater
Coraciidae (25)	Roller
Corvidae (27)	Crow, magpie, jay
Cotingidae (27)	Cotinga
Cracidae (14)	Curassow, guan, chachalaca
Cracticidae (27)	Bell magpie, Australian butcher bird, piping crow
Cuculidae (19)	Cuckoo, anis, roadrunner, coua, coucal
Cyclarhinae (27)	Pepperstrike
Dendrocolaptidae (27)	Woodcreeper, woodhewer
Dicaeidae (27)	Flowerpecker
Dicruridae (27)	Drongo
Diomedeidae (9)	Albatross
Drepanididae (27)	Hawaiian honeycreeper
Dromadidae (16)	Crab-plover
Dromiceiidae (3)	Emu
Dulidae (27)	Palm chat
Emberizinae (27)	Ground finch, New World sparrow, Old World finch, bunting
Estrildidae (27)	Waxbill, grass finch, mannikin, java sparrow
Eurylaimidae (27)	Broadbill
Eurypygidae (15)	Sun-bittern
Falconidae (13)	Falcon
Formicariidae (27)	Antbird
Fregatidae (10)	Frigate-bird
Fringillidae (27)	Cardinal, bunting, sparrow
Furnariidae (27)	Ovenbird
Galbulidae (26)	Jacamar
Gaviidae (7)	Loon
Geospizinae (27)	Galapagos and Cocos Island finch
Glareolidae (16)	Pratincole, courser
Grallinidae (27)	Magpie-lark
Gruidae (15)	Crane
Haematopodidae (16)	Oystercatcher
Heliornithidae (15)	Finfoot, sun grebe
Hemiprocnidae (22)	Crested or tree swift
Hirundinidae (27)	Swallow, martin
Hydrobatidae (9)	Storm petrel
Hypositinae (27)	Coral-billed nuthatch
Icteridae (27)	American blackbird, oriole, troupial
Indicatoridae (26)	Honey-guide
Irenidae (27)	Fairy bluebird, iora, leafbird
Jacanidae (16)	Lily-trotter, jacana
Laniidae (27)	Shrike, butcher-bird
Laridae (16)	Gull, tern
Leptosomatidae (25)	Cuckoo-roller
Megapodiidae (14)	Megapode
Meleagrididae (14)	Turkey
Meliphagidae (27)	Honey-eater
Menuridae (27)	Lyrebird
Meropidae (25)	Bee-eater
Mesoenatidae (15)	Mesite, roatelo, monia
Mimidae (27)	Thrasher, cat bird, mockingbird
Momotidae (25)	Motmot
Motaciilidae (27)	Wagtail, pipit
Muscicapidae (27)	Old World flycatcher
Musophagidae (19)	Turaco, plaintain-eater
Nectariniidae (27)	Sunbird, spider hunter
Numididae (14)	Guinea fowl
Nyctibiidae (21)	Potoo, wood-nightjar
Opisthocomidae (14)	Hoatzin
Oriolidae (27)	Old World oriole
Otididae (15)	Bustard
Pandionidae (13)	Osprey, fish-hawk
Paradisaeidae (27)	Bird of paradise
Paridae (27)	Titmouse, chickadee
Paradoxornithidae (27)	Parrotbill or suthora
Parulidae (27)	Wood warbler, honeycreeper warbler
Pedionominae (15)	Plains-wanderer, collared hemipode
Pelecanidae (10)	Pelican
Pelecanoididae (9)	Diving petrel
Phaëthontidae (10)	Tropic-bird
Phalacrocoracidae (10)	Cormorant
Phalaropodidae (16)	Phalarope
Phasianidae (14)	Pheasant quail, peacock
Philepittidae (27)	Asite or philepitta
Phoeniculidae (25)	Wood-hoopoe
Phoenicopteridae (28)	Flamingo
Phytotomidae (27)	Plant-cutter
Picathartidae (27)	Bald crow
Picidae (26)	Woodpecker, wryneck, piculet
Pipridae (27)	Manakin
Pittidae (27)	Pitta or jewel thrush
Ploceidae (27)	Weaverbird
Podargidae (21)	Frogmouth
Podicepedidae (8)	Grebe
Prionopidae (27)	Helmet shrike or wood shrike
Procellariidae (9)	Petrel, fulmar, shearwater
Prunellidae (27)	Accentor or hedge sparrow
Pseudochelidoninae (27)	African river martin
Psittacidae (18)	Parrot, parakeet, cockatoo, Iory
Psophiidae (15)	Trumpeter
Pteroclidae (17)	Sand-grouse
Ptilonorhynchidae (27)	Bowerbird
Pycnonotidae (27)	Bulbul
Rallidae (15)	Rail, gallinule, coot
Ramphastidae (26)	Toucan
Recurvirostridae (16)	Avocet, stilt
Regulinae (27)	Kinglet or goldcrest
Rheidae (3)	Rhea
Rhinocryptidae (27)	Tapaculo
Rhynochetidae (15)	Kagu
Richmondeninae (27)	Cardinal, grosbeak, saltator
Rostratulidae (16)	Painted snipe
Rynchopidae (16)	Skimmer
Sagittariidae (13)	Secretary bird
Scolopacidae (16)	Sandpiper, snipe, woodcock

TABLE 2. (*Continued*)

Latin Family Name	English Name or Examples
Scopidae (11)	Hammerhead
Sittidae (27)	Nuthatch
Spheniscidae (6)	Penguin
Steatornithidae (21)	Oilbird, guacharo
Stercorariidae (16)	Skua, jaeger
Strigidae (20)	Owl
Struthionidae (1)	Ostrich
Sturnidae (27)	Starling
Sulidae (10)	Gannet, booby
Sylviidae (27)	Old World warbler
Tersinidae (27)	Swallow-tanager
Tetraonidae (14)	Grouse
Thinocoridae (16)	Seed-snipe
Thraupidae (27)	Tanager, diglossa
Threskiornithidae (11)	Ibis, spoonbill
Timaliidae (27)	Babbling thrush
Tinamidae (5)	Tinamou
Todidae (25)	Tody
Trochilidae (22)	Hummingbird
Troglodytidae (27)	Wren
Trogonidae (24)	Trogon
Turdidae (27)	Thrush, blue thrush, forktail, ochoa, robin
Turnicidae (15)	Button quail
Tyrannidae (27)	Tyrant flycatcher
Tytonidae (20)	Barn owl
Upupidae (25)	Hoopoe
Vangidae (27)	Vanga shrike
Vireolaniinae (27)	Shrike-vireo
Vireonidae (27)	Vireo
Xenicidae (27)	New Zealand wren
Zeledoniidae (27)	Wren-thrush
Zosteropidae (27)	White-eye

Identification of Order of which Family is a part:

Order No.	Name of Family
1	Struthioniformes (Ostriches)
2	Rheiformes (Rheas)
3	Casuariiformes (Cassowaries and Emus)
4	Apteryciformes (Kiwis)
5	Tinamiformes (Tinamous)
6	Sphenisciformes (Penguins)
7	Gaviiformes (Loons)
8	Podicepediformes (Grebes)
9	Procellariiformes (Tube-nosed Swimmers)
10	Pelecaniformes (Totipalmate Swimmers)
11	Ciconiiformes (Long-legged Waders)
12	Anseriformes (Waterfowl and Screamers)
13	Falconiformes (Diurnal Birds of Prey)
14	Galliformes (Gallinaeous Birds and Hoatzin)
15	Gruiformes (Rails, Cranes, and Bustard-like Birds)
16	Charadriiformes (Shorebirds, Alcids, and Gull-like Birds)
17	Columbiformes (Pigeon-like Birds)
18	Psittaciformes (Parrot-like Birds)
19	Cuculiformes (Cuckoo-like Birds and Turacos)
20	Strigiformes (Owls)
21	Caprimulgiformes (Nightjars)
22	Apodiformes (Swifts and Hummingbirds)
23	Coliiformes (Mousebirds or Colies)
24	Trogoniformes (Trogons)
25	Coraciiformes (Kingfishers, Todies, Rollers, Hornbills, etc.)
26	Piciformes (Jacamars, Barbets, Toucans, Woodpeckers, etc.)
27	Passeriformes (Perching Birds and Higher Song Birds)
28	Phoenicopteriformes (Flamingos)

The guidance system used by birds in their rather exacting migratory patterns have been studied for a number of years, but much remains to be investigated. A large number of species travel at night and this rules out a high degree of dependence upon visual ground observations for many of them, unless, of course, there is some form of infrared "photographic" detection yet undetected. Some years ago, the concept of a pure memory system was tested by transporting two sets of birds to test their homing abilities. One set was rotated on a turntable while traveling; the other set was not. Both sets homed successfully with no measurable difference in the experiment. Golden plovers cross several thousand miles of open ocean

TABLE 3. ALPHABETICAL LIST OF BIRDS SHOWING LATIN FAMILY NAMES AND ORDERS (Orders are shown by number in ( ) after common name of bird. See note at end of Table 2 for identification of the order.)

Common Name	Family
Accentor (27)	*Prunellidae*
Adjutant (11)	*Ciconiidae*
African river martin (27)	*Pseudochelidoninae*
Albatross (9)	*Diomedeidae*
American blackbird (27)	*Icteridae*
Anhinga (10)	*Anhingidae*
Anis (19)	*Cuculidae*
Antbird (27)	*Formicariidae*
Ant-pipit (27)	*Conopophagidae*
Argus (14)	*Phasianidae*
Asite (27)	*Philepittidae*
Auk (16)	*Alcidae*
Australian butcher bird (27)	*Cracticidae*
Avocet (16)	*Recurvirostridae*
Babbling thrush (27)	*Timaliidae*
Baldcrow (27)	*Picathartidae*
Baldpate (12)	*Anatidae*
Baltimore oriole (27)	*Icteridae*
Barbet (26)	*Capitonidae*
Barn owl (20)	*Tytonidae*
Becard (27)	*Cotingidae*
Bee-eater (25)	*Meropidae*
Bellbird (27)	*Cotingidae*
Bell magpie (27)	*Cracticidae*
Bird of paradise (27)	*Paradisaeidae*
Bittern (11)	*Ardeidae*
Blackbird (American) (27)	*Icteridae*
Bluebird (27)	*Irenidae*
Blue thrush (27)	*Turidae*
Boat-billed heron (11)	*Cochleariinae*
Bobolink (27)	*Icteridae*
Bob White (14)	*Phasianidae*
Bonaparte's gull (16)	*Laridae*
Booby (10)	*Sulidae*
Bowerbird (27)	*Ptilonorhynchidae*
Broadbill (27)	*Eurylaimidae*
Bulbul (27)	*Pycnonotidae*
Bunting (27)	*Emberizinae*
Bustard (15)	*Otididae*
Butcherbird (27)	*Laniidae*
Button quail (15)	*Turnicidae*
California gull (16)	*Laridae*
Canary (27)	*Carduelinae*
Canvasback (12)	*Anatidae*
Cardinal (27)	*Richmondeninae* also *Fringillidae*
Cariama (15)	*Cariamidae*
Cassowary (3)	*Casuariidae*
Cat bird (27)	*Mimidae*
Chachalaca (14)	*Cracidae*
Chaffinch (27)	*Fringillidae*
Chat (27)	*Icteridae*
Chickadee (27)	*Paridae*
Chicken (14)	*Phasianidae*
Chough (27)	*Corvidae*
Cochoa (27)	*Turidae*
Cockatoo (18)	*Psittacidae*
Cock-of-the-Rock (27)	*Cotingidae*
Collared hemipode (15)	*Pedionominae*
Coly (23)	*Coliidae*
Condor (13)	*Cathartidae*
Coot (15)	*Rallidae*
Coral-billed nuthatch (27)	*Hypositinae*
Cormorant (10)	*Phalacrocoracidae*
Cotinga (27)	*Cotingidae*
Coua (19)	*Cuculidae*
Coucal (19)	*Cuculidae*
Courser (16)	*Glareolidae*
Cowbird (27)	*Icteridae*
Crab-plover (16)	*Dromadidae*
Crake (15)	*Rallidae*
Crane (15)	*Gruidae*

TABLE 3. (*Continued*)

Common Name	Family
Creeper (27)	*Certhiidae*
Crested argus (14)	*Phasianidae*
Crested swift (22)	*Hemiprocnidae*
Crocodile Bird (16)	*Glareolidae*
Crossbill (27)	*Carduelinae*
Crow (27)	*Corvidae*
Cuckoo (19)	*Cuculidae*
Cuckoo-roller (25)	*Leptosomatidae*
Cuckoo-shrike (27)	*Campephagidae*
Curassow (14)	*Cracidae*
Curlew (11)	*Scolopacidae*
Currawong (27)	*Cracticidae*
Diamond bird (27)	*Dicaeidae*
Diglossa (27)	*Thraupidae*
Dipper (27)	*Cinclidae*
Diver (7)	*Gaviidae*
Diving petrel (9)	*Pelecanoididae*
Dollarbird (25)	*Coraciidae*
Dotterel (16)	*Charadriidae*
Dove (17)	*Columbidae*
Dovekie (16)	*Alcidae*
Dowitcher (16)	*Scolopacidae*
Drongo (27)	*Dicruridae*
Duck (12)	*Anatidae*
Dunlin (16)	*Scolopacidae*
Dunnock (27)	*Prunellidae*
Eagle (13)	*Accipitridae*
Egret (11)	*Ardeidae*
Eider (12)	*Anatidae*
Emu (3)	*Dromiceiidae*
Fairy bluebird (27)	*Irenidae*
Falcon (13)	*Falconidae*
Finch (most species) (27)	*Emberizinae*
Finfoot (15)	*Heliornithidae*
Fire-backed pheasant (14)	*Phasianidae*
Fish-hawk (13)	*Pandionidae*
Flamingo (28)	*Phoenicopteridae*
Flowerpecker (27)	*Dicaeidae*
Flycatcher, Old World (27)	*Muscicapidae*
Forktail (27)	*Turidae*
Franklin's gull (16)	*Laridae*
Frigate-bird (10)	*Fregatidae*
Frogmouth (21)	*Podargidae*
Fulmar (9)	*Procellariidae*
Galapagos and Cocos Island finch (27)	*Geospizinae*
Gallinule (15)	*Rallidae*
Gambel's quail (14)	*Phasianidae*
Gannet (10)	*Sulidae*
Gnat-eater (27)	*Conopophagidae*
Goatsucker (21)	*Caprimulgidae*
Godwit (11)	*Scolopacidae*
Goldcrest (27)	*Regulinae*
Golden pheasant (14)	*Phasianidae*
Goose (12)	*Anatidae*
Grass finch (27)	*Estrildidae*
Gray Lag (12)	*Anatidae*
Grebe (8)	*Podicepedidae*
Greenbul (27)	*Pycnonotidae*
Greenlet (27)	*Vireonidae*
Greenshank (16)	*Scolopacidae*
Grosbeak (27)	*Richmondeninae*
Ground finch (27)	*Emberizinae*
Ground roller (25)	*Brachypteraciidae*
Grouse (14)	*Tetraonidae*
Guacharo (21)	*Steatornithidae*
Guan (14)	*Cracidae*
Guillemot (16)	*Laridae*
Guinea fowl (14)	*Numididae*
Gull (16)	*Laridae*
Hammerhead (11)	*Scopidae*
Harlequin (12)	*Anatidae*
Harrier (Old World) (13)	*Accipitridae*
Hawaiian honeycreeper (27)	*Drepanididae*
Hawk (13)	*Accipitridae*
Hedge sparrow (27)	*Prunellidae*
Helmet shrike (27)	*Prionopidae*
Heron (11)	*Ardeidae*
Herring gull (16)	*Laridae*
Hoatzin (14)	*Opisthocomidae*
Honeycreeper warbler (27)	*Parulidae*
Honey-eater (27)	*Meliphagidae*
Honey-guide (26)	*Indicatoridae*
Hoopoe (25)	*Upupidae*
Hornbill (25)	*Bucerotidae*
Huias (27)	*Callaeidae*

Yellow-leg (11)	*Scolopacidae*
Yokohama chicken (14)	*Phasianidae*

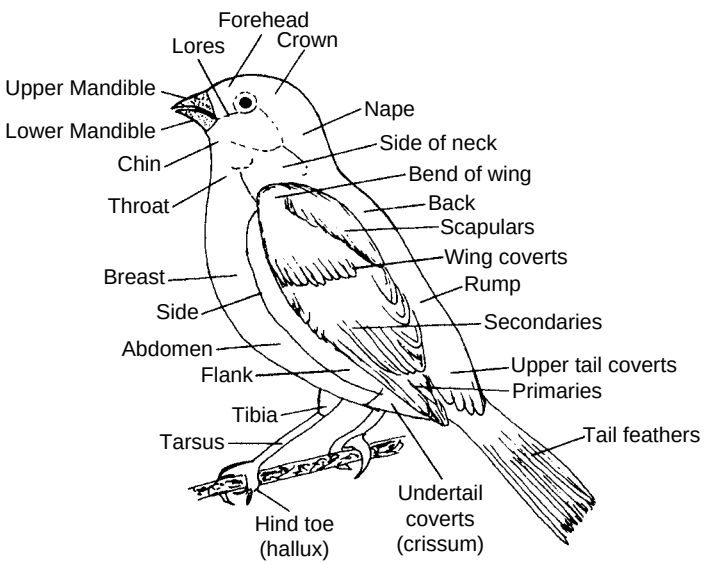

Fig. 2. Major external features of "typical" bird.

between Hawaii and Alaska; the New Zealand bronze cuckoo travels about 2500 miles (4023 kilometers) over the open ocean between New Zealand, the Bismarck and Solomon Islands. Curlews travel over the ocean from Tahiti and Alaska, a distance of well over 5500 miles (8850 kilometers). In some instances, young birds make these flights for the first time without receiving directions from adults. Migratory speeds and stamina also are most impressive. In an experiment, an albatross was released over 3000 miles (4827 kilometers) from its regular habitat on Midway Island. The bird returned home in 10 days, or an average speed of 300 miles (483 kilometers) per day.

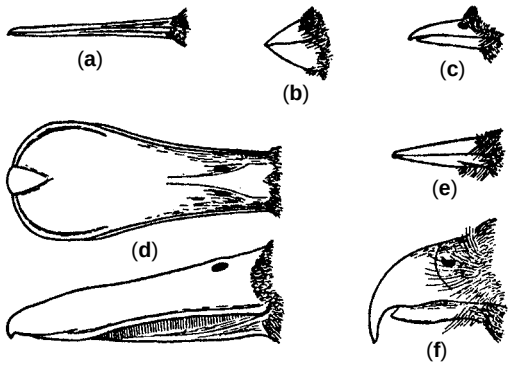

Fig. 3. The beaks of birds: (**a**) yellow legs, a wader; (**b**) cardinal, a seedeater; (**c**) flycatcher, an insect eater; (**d**) the shoveler duck, dorsal surface above and side view showing the lateral sieve below; (**e**) a woodpecker's chisel-tipped beak; (**f**) hawk, a bird of prey.

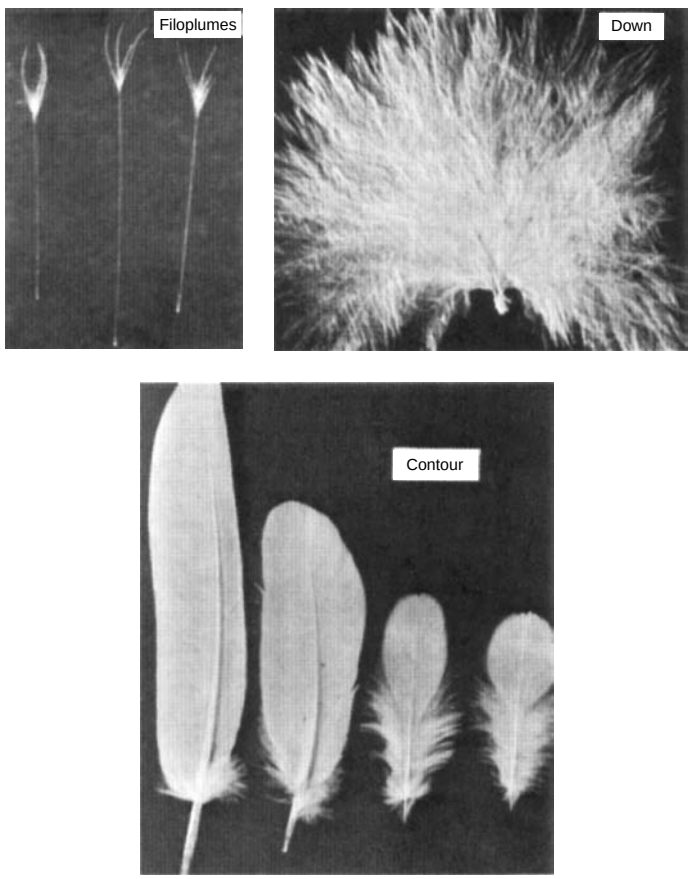

Fig. 4. The three types of bird feathers. The filoplumes and down are shown much enlarged. (*A.M. Winchester*.)

Some authorities have proposed that the earth's magnetic field may provide guidance parameters, but any connection has yet to be fully demonstrated. The use of the position of the sun by daytime migrators, in which compensation is made for the changing angle of the sun, was demonstrated by the late German scientist Gustav Kramer. The use of celestial navigation by nighttime migrators also has been extensively studied, with some relatively convincing results. Numerous techniques have been developed for marking and tracking birds and perhaps one day the riddle of navigation by the migrators may yield to constant probing.

Internal Rhythms Versus External Signals. Without convincing proofs of the possible roles of external navigation signals, many scientists have turned to endogenous mechanisms.

Extensive studies of bird migration were conducted over a period of nearly five decades by scientists at the Vogelwarte Radolfzell Institute, located in southern Germany; most of the findings in this article were reported by these scientists. However, other research groups in this field

include R.E. Moreau (Edward Grey Institute, UK) and Wolfgang Wiltschko (University of Frankfurt), among many other scientists throughout the world.

Researchers have categorized bird migratory paths into three great systems: (1) the Palearctic–African[1] System, (2) the North America–Central and South America System, and (3) the Northeastern Asia–Southeastern–Australia System. These systems encompass the flight paths of numerous bird species.

The greatest numbers of birds spend summers in temperate zones and either migrate south or north for their winters. Probably the most studied of these regions is the Palearctic–African System, largely because many of these studies commenced in Europe during the early 1900s.

It is estimated that over 60 million birds have been banded in Europe, of which over a million have been recovered. However, it is further estimated that 5 billion birds fly from Africa to Europe within a given year. The length of the migratory path varies greatly from one species to another. For example, it has been determined that the woodcock will travel a few hundred kilometers across the Mediterranean, whereas the Siberian ruff travels over 12,000 kilometers, spanning Asia and eastern Europe before arriving in central Africa, the winter home of the species. Compared with other long-distance flights, the foregoing is not a record.

Gwinner and research associates (Ornithological Station of the Max Planck Institute for Behavioral Physiology) have concentrated their studies on two species of warbler — i.e., the blackcap warbler (*Sylvia atricapilla*) and the garden warbler (*S. borin*). Some studies also have been conducted of the flycatcher (*Muscicapidae*).

For their studies, three main questions were addressed:

1. How is timing of migration controlled?
2. How can a bird navigate to a specific target area on each leg of the migration?
3. How can a bird fly such long distances, often across oceans or deserts, without means for replenishing its energy reserves?

Further it was asked, "Where does the impulse come from that guides the birds toward warmer climates in winter and brings them back to their northern breeding grounds in the spring?" Unfortunately, not one of these questions has been answered satisfactorily to date.

Additional questions seeking answers include the formational manner in which birds fly during migration, such as the neat V-formation of Canadian geese and the helter-skelter patterns of groups of starlings.

Concerning a bird's urge to commence migration, is it an external, environmental signal, such as temperature or duration of daylight hours? Because temperature, in particular, alternately can be changed a number of times once migration has commenced, the bird would be "advised" to turn backward, then forward, and so on. Other external factors studied in recent years include the effect of artificially altering light exposure among captive birds. Currently, the consensus of experts in recent years is that causes of rhythm endogenous to the bird must account for the major factors that govern migration. These annual cycles appear to determine not only the timing of migration but also a number of detailed navigational factors for specific targets. The latter, to date, are poorly understood. Studies do indicate that these cycles can be modified somewhat by environmental factors and by young birds learning from older birds. It is interesting to note that the navigation systems of inexperienced birds differ from those of birds who have made the trip at least once. Tagging studies have indicated that inexperienced birds tend to stay on a constant course from origin to destination, whereas experienced birds compensate their path to avoid, for example, unduly high mountain peaks and broad expanses of oceans, preferring island hopping where this is feasible.

To make such determinations, Perdeck (Institute for Evolutionary and Ecological Research, the Netherlands) (*http://wwwbio.leidenuniv.nl/~eew/indexr.html#Board*) captured starlings midway along a typical migratory path and transported and tagged them at a second (alternate) flight origin some distance away. This was required, of course, because otherwise the inexperienced birds simply would fly along with the experienced birds.

In reporting on his studies, Gwinner described a number of experiments used to determine "restlessness," a behavioral quality that progressively appears in a bird as migration time nears. In one experiment, restlessness was monitored by determining the number of times in a given span of time that the captive bird left one perch for another in a specially constructed cage. An electronic switch on one of the perches and a time recorder were used. Periods of light exposure, temperature change, and so on were altered over brief and long periods — seemingly without effect on the bird's "natural" year-round timing. Many interesting correlations were developed that showed consistency with other rhythmic bird behavior, such as molting.

Experiments to date make a strong argument that a single directional heading may be endogenous to each bird species. Experiments have been made where migrating birds were captured, moved several miles, and then released, after which the identical heading was followed. This, of course, caused the birds to land either to the left or the right of the previously "set" course.

Research into what migrating birds do and do not do will form a framework for future learning of how they do it! The answers most likely will be found through intense physiological and biochemical studies of the bird's internal mechanisms. Just as hormones and brain chemicals appear to control the timing and manner of breeding and molting, the answers to navigation and other unexplained aspects of migration may be found in a bird's biochemistry.

Vocalism of Birds

Communication among birds, particularly of a given species, has been studied for a number of years. The development of convenient and portable tape recorders of excellent quality has provided the principal research tool. Computer sound analysis also has contributed greatly to this research. Classification of bird sounds using the comparatively recent science of bioacoustics is headquartered at the Bioacoustic Research Center, Cornell University, Ithaca, New York. As of the early 1990s, over 65,000 recordings were on file in the collection. There is a similar program in Sweden.

Although some birds seem voiceless, it is usually found that they chatter with their bills to make the necessary signals and noises required for notification of danger, in courting, and in seeking food. Some of the specific attributes and characteristics of numerous species are described elsewhere in this volume. Consult Table 1 and *Alphabetical Index*.

With considerable success in recording bird sounds, the methodologies have been extended to include numerous other animals, such as dolphins, whales, and gorillas. In an interesting case, the ivory-billed woodpecker had been considered extinct for many years, but was rediscovered later in Cuba with the aid of a recording made with crude equipment in 1935.

Bird sounds also have been used in an entirely different avenue of research. Nottebohn (Rockefeller University) reported on studies of song-control centers in the canary brain and found that new nerve cells are produced in adulthood to replace older cells. Traditionally, it has been postulated that neurogenesis does not take place in adults, including humans, once the brain has been fully developed. If more can be learned from avian brain studies, perhaps this may shed new light on possible human neurogenesis in adults.

Researchers have shown that, in the male canary, vocalism develops in four distinct phases:

1. *Food begging*, consisting of shrill and high-pitched calls, present for about four weeks after birth.
2. *Sub-song*, when the first attempts to sing are evidenced. The sounds are of low volume.
3. *Plastic song*, consisting of variable qualities, but with improved structure and some indication of the stereotyped quality to follow.
4. *Stable song*, which persists during the mating season, but which deteriorates to *plastic song* until the next mating season.

Again, there is evidence of year-round rhythm. There is a correlation between the bird's type of song and his testosterone blood levels.

Endangered Bird Species

The Endangered Species Act (U.S.) (the Act) has been in effect for more than two decades. There have been a few successes in terms of birds:

1. There were about 300 nesting pairs of the American bald eagle in the 1960s. These had increased to about 3000 pairs by the early 1990s.
2. During the same time frame, the whooping crane increased from a flock of about 20 to one of approximately 200 in the early 1990s.

However, conservationists and environmentalists are even more concerned today than when the Act was originally created.

The endangerment of numerous other birds is described in this volume in their species descriptions. Check Alphabetical Index.

[1] The Palearctic is a biogeographical region that includes Europe, Asia north of the Himalayas, northern Arabia, and Africa north of the Sahara.

Much has been learned since the passage of the Act, and a new science, *ecological pathology*, has been created — this because the problem indeed has become more difficult to express in scientific terms, as contrasted with essentially qualitative observations. Initially, exposure to chemicals (insecticides, herbicides, etc.) was comparatively easy to prove scientifically, and, in fact, in most of the world it was a matter relatively easy to control. The effects of deforestation have turned out to be easy to qualify, but not necessarily simple to quantify. Further, the matter of economic viability becomes a key factor in such situations. Deforestation is particularly troublesome in connection with birds because of the annual long-distance migrations of many species. Thus, two habitats are introduced — not only the temperate conditions–forests where birds breed and nest, but the tropical forests where many species live during winter.

Also because of the vast numbers of bird species, there results an extremely large and arduous task of observing and counting (field work), followed by critical statistical analysis. The problem has proved much more difficult than was initially envisioned.

Importance of Birds to the Economy

The economic importance of birds is great, and is chiefly to their credit. Insect-eating species destroy countless pests and seed-eating species aid in checking the spread of many weeds, although they may also rob the farmer of a small part of his crops. Scavengers like the turkey vultures are useful, although the degree of their usefulness is difficult to estimate. On the other hand, a few hawks and owls — and only a few — do some harm by destroying useful birds and the crow is given a very bad reputation by conservation experts as a robber of the nests of other birds. It is scarcely necessary to mention the value of birds as food and game. The domestic species, chickens, ducks, turkeys, geese, are too well known as food, and their eggs are too common a culinary material to be readily overlooked. See also **Aves (Birds)**.

BIRKELAND CURRENTS. A Birkeland current generally refers to a system of electrical currents flowing along the direction of the earth's magnetic field, between the outer regions of the magnetosphere and the ionosphere. They are caused by the movement of a plasma perpendicular to a magnetic field. Birkeland currents often show filamentary, or twisted "rope-like" magnetic structure. They are sometimes referred to as *field-aligned currents*.

Originally Birkeland currents referred to electric currents that contribute to the aurora, caused by the interaction of the plasma in the Solar Wind with the Earth's magnetosphere. See Fig. 1. The current flows earthwards down the morning side of the Earth's ionosphere, around the polar regions, and spacewards up the evening side of the ionosphere. These Birkeland currents are now sometimes called auroral electrojets. The currents were predicted in 1903 by Norwegian explorer and physicist Kristian Birkeland, who undertook expeditions into the Arctic Circle to study the aurora.

Professor Emeritus of the Alfvén Laboratory in Sweden, Carl-Gunn Fälthammar wrote (1986): "A reason why Birkeland currents are particularly interesting is that, in the plasma forced to carry them, they cause a number of plasma physical processes to occur (waves, instabilities, fine structure formation). These in turn lead to consequences such as acceleration of charged particles, both positive and negative, and element separation (such as preferential ejection of oxygen ions). Both of these classes of phenomena should have a general astrophysical interest far beyond that of understanding the space environment of our own Earth."

Characteristics

Auroral Birkeland currents can carry about 1 million amperes (Germany, et al.). They can heat up the upper atmosphere which results in increased drag on low-altitude satellites.

Birkeland currents can also be created in the laboratory with multi-terawatt pulsed power generators. See Fig. 2. The resulting cross-section pattern indicates a hollow beam of electron in the form of a circle of vortices, a formation called the *diocotron instability* (Plasma Phenomena: Web Ref.) (similar, but different to the Kelvin-Helmholtz instability), that subsequently leads to filamentation. Such vortices can be seen in aurora as "auroral curls" http://www.phys.ucalgary.ca/trondsen/pai/Curls.html.

Birkeland currents are also one of a class of plasma phenonena called a z-pinch, so named because the azimuthal magnetic fields produced by the current pinches the current into a filamentary cable. This can also twist, producing a helical pinch that spirals like a twisted or braided rope, and this most closely corresponds to a Birkeland current. Pairs of parallel Birkeland currents can also interact; parallel Birkeland currents moving in the same direction will attract with an electromagnetic force inversely proportional to their distance apart (Note that the electromagnetic force between the individual particles is inversely proportional to the *square* of the distance, just like the gravitational force); parallel Birkeland currents moving in opposite directions will repel with an electromagnetic force inversely proportional to their distance apart. There is also a short-range circular component to the force between two Birkeland currents that is opposite to the longer-range parallel forces (The Electromagnetic Force Web Ref).

Electrons moving along a Birkeland current may be accelerated by a plasma double layer. If the resulting electrons approach relativistic velocities (ie. the speed of light) they may subsequently produce a Bennett pinch, which in a magnetic field will spiral and emit synchrotron radiation that includes radio, optical (i.e., light), x-rays, and gamma rays.

BIRTH PROCESS. A type of stochastic process describing the progress of a population for which, at each time point, there is a probability that an individual gives birth to a new individual or new individuals. Likewise, a *Death Process* is one for which an individual has a certain probability of death. More general processes can take account of birth, death, immigration and emigration.

A similar process in which individuals give rise to new ones is sometimes known as a *Branching Process*. Applications are found in many fields, from human populations to particle physics.

BISE. See **Winds and Air Movement**.

BISERIAL CORRELATION. Suppose we have a $2 \times q$ table of frequencies. If it is assumed that the table has arisen by grouping a sample from a bivariate normal distribution, an estimate of the correlation coefficient ρ can be obtained. Such an estimate is known as a biserial correlation coefficient. A slightly different concept, which avoids the above assumptions, is the point-biserial correlation coefficient. This is a measure of association between a continuous variate x and a discrete variate y that takes only two values (0 and 1, for example).

BISHOP, J. MICHAEL (1936–). J. Michael Bishop wrote in his autobiographical essay for the Nobel Foundation that his "youth held little forecast of a career in biomedical research" and, indeed, it was not until he was in his early twenties that he developed a passion for molecular biology.

Bishop was born on 22 February, 1936 in York, Pennsylvania, a rural area as evidenced by the two-room school in which Bishop received his elementary education. The curriculum included very little science but the teaching was rigorous and inspired, and Bishop developed a lifelong interest in history. His father was a Lutheran minister and his home environment fostered another lifelong passion, for music. Bishop's interest in biology was stimulated by his family's physician and Bishop entered Gettysburg College, Pennsylvania, for pre-medical studies. Despite the attractions of history, philosophy and English literature (under which spell Harold Varmus, his later collaborator, also fell), Bishop graduated with a degree in chemistry in 1957.

At this stage, Bishop had leanings to becoming a university teacher and went to Harvard Medical School to pursue that goal. However, once at Harvard, it became apparent that academic success depended less on one's qualities as a teacher than on one's achievements in research. Fortunately, Bishop realized that research was an attractive proposition and he was aided by the kindnesses of Benjamin Castleman and Edgar Taft who provided facilities for Bishop in the department of pathology. Furthermore, Bishop discovered the world of animal virology through an elective course under Elmer Pfefferkorn and he was permitted to spend his final year in medical school doing virology research rather than following the set curriculum.

Bishop graduated from Harvard in 1962 and then spent 2 years as an intern and assistant resident at Massachusetts General Hospital. It was then that he turned to a career in research, with Leon Levintow in the Laboratory of Biology of Viruses within the National Institute of Allergy and Infectious Diseases (NIAID). Bishop worked on the replication of poliovirus in cells growing in tissue culture. It was in this period that Bishop published his first paper and had his first experience of working in a foreign laboratory when he spent one year in Germany. At the end of his fellowship at NIAID, Bishop was offered a post on the East Coast and also on the West Coast at the University of California, San Francisco (UCSF) where Leon Levintow had joined the faculty in the Department of Microbiology and Immunology. Bishop, feeling that he would be a "mere embellishment" at an East Coast Ivy League University, went to UCSF where he has lived and worked since 1968.

Although at first Bishop continued his work on poliovirus, a colleague, Warren Levinson, was working on Rous sarcoma virus (RSV). This, a retrovirus with a genome of RNA rather than DNA, causes cancer in chickens and had been discovered by Peyton Rous in 1911. (Rous received the Nobel Prize in 1966, surely the longest interval between a discovery and its recognition by the Nobel Committee.) Levinson, Lewintow and Bishop began work on how RSV replicated inside cells –what happened to its RNA after infection? But they were forestalled by Howard Temin and David Baltimore who discovered an enzyme, reverse transcriptase, with the remarkable property of making DNA copies of the RSV RNA genome. Inspired rather than deterred by being scooped, Bishop used new experimental strategies that reverse transcriptase permitted to investigate the mechanisms of RSV replication in detail. See also **Baltimore, David (1938–Present)**; **Rous, Francis Peyton (1879–1970)**; and **Temin, Howard Martin (1934–1994)**.

1970 was a momentous year. As Bishop wrote later, the arrival of Harold Varmus as a postdoctoral fellow "changed my life and career." A remarkable synergy developed between them and they began a joint attack on the question of how tumour viruses like RSV make normal cells become cancerous, a process known as transformation. It was assumed that the DNA copies that retroviruses made of their RNA genomes entered the chromosomes of the infected cell and somehow initiated changes that led to transformation. Genetic analysis of RSV mutants had shown that transformation was the property of a gene called *sarc* (from *sarc*oma but later shortened to *src*). See also **Varmus, Harold Elloit (1939–Present)**.

As a first step to analyzing the functions of the gene, Bishop, Varmus and a postdoctoral fellow, Dominique Stehelin, prepared a DNA fragment (probe) that would detect *src*. They did this by taking advantage of RSV mutants that could still infect cells but did not transform them. These mutants were missing pieces of their genome and the assumption was that this missing section of DNA contained the *src* gene responsible for transformation. The experiment appeared to have worked. The probe detected *src* in Rous sarcoma virus DNA but not in mutants unable to transform cells, and *src* was not found in other chicken viruses. A further check was to test the *src* probe on uninfected cells; these should not have *src* because it was the virus that carried it into cells. To their amazement, they found that normal, uninfected chicken cells had *src*!

The conclusion was inescapable that *src* was a normal chicken gene that had a role in normal cell activities; somehow, the Rous sarcoma virus had hijacked this gene that had become altered so that it forced infected cells to multiply uncontrollably, presumably to the benefit of the virus. This conclusion was reinforced by the finding that *src* was present not only in chickens but also in other birds and mammals. The finding was so significant because it suggested that a cell might contain many genes

(proto-oncogenes) that when mutated could cause cancer. Although it soon became clear that retroviral infections were, at the most, extremely rare causes of cancer in human beings, this discovery focused attention on genes controlling key pathways in the normal cell, for example, those controlling cell replication. See also **Oncogenes**.

Bishop became a full professor at UCSF in 1973; Director of the George William Hooper Research Foundation at UCSF in 1981; a University Professor in 1994, and, most recently Chancellor of the University of California. He plays a very active role in matters of science policy, including, for example, serving as a member, and later chair, of the National Cancer Advisory Board, both Presidential appointments. He was also a member of the Commission on the Life Sciences (National Research Council) for ten years.

Bishop shared the 1989 Nobel Prize for Physiology or Medicine with his long time collaborator Harold Varmus. They have shared numerous other honors, most notably the Albert Lasker Basic Medical Research Award and the Alfred P. Sloan Prize from the General Motors Cancer Research Foundation. Bishop became a member of the National Academy of Sciences in 1980. See also **Cancer Research (The History)**.

Bishop is an avid supporter of the San Francisco Giants baseball team. One of his most eagerly anticipated rewards associated with winning the Nobel Prize was to throw out the first ball in Game 4 of the 1989 World Series between the Giants and the Oakland A's in Candlestick Park, San Francisco. Unfortunately, the Loma Prieta earthquake (Richter magnitude 7.1) occurred on the first day of Game 3. The game was cancelled, the schedule changed, and Bishop was reassigned to Game 5. But it did not take place –the A's won in four straight games.

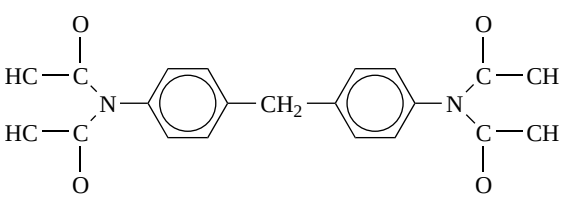
BISMALEIMIDE POLYMERS. These relatively new polymeric materials were developed to serve the increasing requirements for materials of high strength in high-temperature applications. Currently, a high percentage of the bismaleimides produced are used for printed circuit boards (PCBs). The materials usually are cured with aromatic amines and then compression molded into the PCBs. Future uses include aircraft structural components where bismaleimides may prove superior for high-temperature skin surface applications as compared with present epoxy composites.

Bismaleimides are produced by the condensation reaction of a diamine, such as methylenedianiline, with maleic anhydride. The reaction product tends to be crystalline with a high melting point. Eutectic blends of different bismaleimides reduce the melting point. However, a co-reactant generally is required to improve the processing properties of the material. Bismaleimides owe their reactivity to the double bonds on each end of the molecule, which can react with themselves or with other compounds containing functional groups (vinyls, allyls, or amines). A typical bismaleimide structure is shown by:



Bismaleimides require an initial cure of from 350 to 450 °F (177 to 232 °C) for one to four hours, followed by a postcure at 450 °F (232 °C) for four hours, if the full properties are to be developed. The glass transition temperature of bismaleimides generally exceeds 500 °F (260 °C). The materials generally have a continuous-use temperature of from 400 to 450 °F (204 to 232 °C).

Compounds based on allyl phenols, such as diallyl bisphenol A, are a recent development. These compounds have superior mechanical properties, processing, and toughness. Some of these compounds are liquids that can dissolve the bismaleimide and thus result in a resin system that is suitable for filament winding and casting in addition to fiber impregnation. When allyl phenols are used as co-curing agents with bismaleimides, the gains in strength and toughness at room and elevated temperatures are marked. Hot acid resistance is also outstanding. Coating applications are developing where resistance to acids and high temperatures are required.

BISMUTH. [CAS 7440-69-9] Chemical element, symbol Bi, at. no. 83, at. wt. 208.981, periodic table group 15, mp 271.3 °C, bp 1555–1565 °C, density 9.75 g/cm^3 (20 °C). Elemental bismuth has a rhombohedral crystal structure. The metal is of a silvery-white color with limited ductility. Like gallium, bismuth is one of the few metals that increases its volume (3.32%) upon solidifying from the molten state. It is the most diamagnetic of all the metals. All isotopes of the element (^{205}Bi through ^{215}Bi) are radioactive. See also **Radioactivity**. However, the naturally occurring isotope ^{209}Bi generally is not regarded in this category because of its extremely long half-life (2×10^{17} years). Although described by Basil Valentine in the fifteenth century, the element was not defined as a new element until its characteristics were published in 1753 by C. Geoffroy and T. Bergman.

First ionization potential 7.287 eV; second 16.6 eV; third 25.56 eV; fourth 45.1 eV; fifth 55.7 eV. Oxidation potentials $Bi + H_2O \rightarrow BiO^+ + 2H^+ + 3e^-$, -0.32 V; $Bi + 3OH^- \rightarrow BiOOH + H_2O + 3e^-$, 0.46 V. Other important physical characteristics of bismuth are given under **Chemical Elements**.

Bismuth occurs as native bismuth in Bolivia and Saxony and frequently is associated with lead, copper, and tin ores—the sulfide (bismuthinite, bismuth glance, Bi_2S_3) is also found in nature. Separation of bismuth from lead takes place during the electrolytic refining of the latter with bismuth remaining in the anode mud, or by prometallurgical methods by which it is removed from the lead as a calcium-magnesium compound. See also **Bismuthinite**.

Alloys. Metallurgically, bismuth is used in the production of low melting point fusible alloys and as an additive to steel, cast iron, and aluminum. The fusible alloys contain about 50% bismuth in combination with lead, tin, cadmium, and indium and are used in a variety of ways, including fire-protection devices, joining and sealing hardware, and short-life dies. Because of the special volume-increase property with solidification, bismuth is used to manufacture alloys with a zero liquid-to-solid volume change. Alloy compositions are given in Table 1. The addition of about 0.2% bismuth, along with a similar quantity of lead, improves the machine-ability of aluminum. Very small quantities (0.02%) of bismuth are used in the production of malleable cast iron for stabilization of carbides upon solidification, particularly desirable for castings with heavy cross sections. Combinations of bismuth and tin and bismuth and cadmium have found use as counterelectrode alloys in the manufacture of selenium rectifiers. Bismuth telluride Bi_2Te_3 and bismuth selenide Bi_2Se_3 display thermoelectric properties. With modification, these compounds are

TABLE 1. SOME REPRESENTATIVE LOW-MELTING-POINT ALLOYS CONTAINING BISMUTH

Fusible alloy, melting at 96 °C	53% Bi	32% Pb	15% Sn
Fusible alloy, melting at 91.5 °C	52% Bi	40% Pb	8% Cd
Fusible alloy, melting at 100 °C	50% Bi	30% Sn	20% Pb
Fusible alloy, melting at 70 °C. (Wood's metal)	50% Bi	25% Pb	12.5% Sn 12.5% Cd
Fusible alloy, melting at 70 °C. (Lipowitz' alloy)	50% Bi	27% Pb	13% Sn 10% Cd
Rose metal	50% Bi	27% Pb	23% Sn
Bismuth solder, melting at 111 °C.	40% Bi	40% Pb	20% Sn

used for certain commercial and military solid-state devices, including small units for portable power generation and refrigeration.

In 1912, a number of bronze artifacts from Late Horizon times (A.D. 1476–1534) were recovered at the Inca city of Machu Picchu in Peru. These were among the first artifacts ever to be subjected to metallographic studies. Researchers Gordon and Rutledge (Kline Geology Laboratory, Yale University) reported in 1984 that the decorative bronze handle of a tumi (small knife) excavated at the Inca city contains 18% bismuth and appears to be the first known example of the use of Bi with Sn to make bronze. The alloy is not made brittle by the Bi because the bismuth-rich constituent does not penetrate the grain boundaries of the matrix phase. The use of Bi facilitated the duplex casting process by which the tumi was made and forms an alloy of unusual color.

Chemistry and Compounds. Generally, the chemical behavior of bismuth parallels that of arsenic and antimony, but bismuth is the most metallic of the group. Bismuth is not soluble in cold H_2SO_4 or cold HCl, but is attacked by these acids when hot and also by cold aqua regia. Elemental bismuth is not attacked by cold alkalies. The metal is soluble in HNO_3 and forms nitrates. When heated with chlorine, bismuth yields a chloride.

Some of the salts of bismuth are used in medicines for the relief of digestive disorders because of the smooth, protective coating the compounds impart to irritated mucous membranes. Like barium, bismuth also is used as an aid in x-ray diagnostic procedures because of its opacity to x-rays. At one time, certain bismuth compounds were used in the treatment of syphilis. Bismuth oxychloride, which is pearlescent, has found use in cosmetics, imparting a frosty appearance to nail polish, eye shadow, and lipstick, but may be subject to increasing controls. Bismuth phosphomolybdate has been used as a catalyst in the production of acrylonitrile for use in synthetic fibers and paints. Bismuth oxide and subcarbonate are used as fire retardants for plastics.

Bismuth trihalides exhibit an increased tendency toward hydrolysis, usually forming bismuthyl compounds, also called bismuth oxyhalides, which are often assumed to contain the ion BiO^+. This is not a discrete ion, however, and the crystal lattices of the "bismuthyl" compounds actually are comprised of Bi(III), O(−II) and X(−I) units. For example, BiOCl has the same crystal structure as PbFCl. The trihalides also form halobismuthates, with halogen ions, such as the chlorobismuthates, which contain the ions $BiCl_4^-$ and $BiCl_5^{2-}$. The BiI_4^{2-} ion is precipitated analytically as the cinchonine salt.

Bismuth(III) oxide [CAS: 1304-76-3], Bi_2O_3, is the compound produced by heating the metal, or its carbonate, in air. It is definitely a basic oxide, dissolving readily in acid solutions, and unlike the arsenic or antimony compounds, not amphiprotic in solution, although it forms stoichiometric addition compounds on heating with oxides of a number of other metals. It exists in three modifications, white rhombohedral, yellow rhombohedral, and gray-black cubical. Bismuth(II) oxide, BiO, has been produced by heating the basic oxalate.

Bismuth(III) hydroxide also is not significantly amphiprotic in solution, dissolving only in acids. Its formula is given as $Bi(OH)_3$ but it is difficult to isolate, due to adsorption of acid anions and to its dehydration to BiO(OH). The action of strong oxidants in concentrated alkalies on the hydroxide yields alkali bismuthates, such as $NaBiO_3$, sodium metabismuthate, from which $NaBi(OH)_6$ is initially produced. Other metal bismuthates may be made from them or directly from the oxides and Bi_2O_3, and bismuth(V) oxide is obtained by the action of HNO_3 on the alkali bismuthates; however, some oxygen is lost and the product is a mixture of Bi_2O_5 and BiO_2.

Bismuth(III) sulfide [CAS: 1345-07-9], Bi_2S_3, is precipitated by H_2S from bismuth solutions. Complex sulfide ions form only slowly, so bismuth sulfide may be separated from the arsenic and antimony sulfides by this difference in properties. Like the oxide, bismuth sulfide forms double compounds with the sulfides of the other metals.

Bismuth vanadate, $BiVO_4$, exhibits a ferroelastic-paraelastic phase transition and had been the subject of considerable investigation. This is reported in some detail in the entry on **Vanadium**.

Bismuth forms a number of complex compounds, including the sulfatobismuthates, e.g., $NaBi(SO_4)_2$ and $Na_3Bi(SO_4)_3$; and the thiocyanatobismuthates, e.g., $Na_3Bi(SCN)_6$, by the interaction of sodium thiocyanate and $Bi(SCN)_3$. The salts of bismuth tend to lose part of their acid readily, especially on heating, to form basic salts.

True pentavalent compounds of bismuth are rare, but include bismuth pentafluoride, BiF_5 (subl. 550 °C), and $KBiF_6$; pentaphenylbismuth, $(C_6H_5)_5Bi$; various compounds $(C_6H_5)_3BiX_2$, where X = F, Cl, Br, N_3, NCO, CH_3CO_2, $\frac{1}{2}CO_3$; and tetraphenylbismuthonium salts, $[(C_6H_5)_4Bi]X$, where X = Cl, $-[B(C_6H_5)_4]$, etc.

Organobismuth Compounds. Numerous bismuth organic compounds have been prepared. Some of these include methylbismuthine CH_3BiH_2; phenyldibromobismuthine $C_6H_5BiBr_2$; potassium diphenylbismuthide $K[Bi(C_6H_5)_2]$; triphenylbismuthdihydroxide $(C_6H_5)_2Bi(OH)_2$; tetraphenylbismuthonium tetraphenylborate $[(C_6H_5)_4Bi]$ $[B(C_6H_5)_4]$; and pentaphenylbismuth $(C_6H_5)_5Bi$.

BISMUTHINITE. A mineral containing a sulfide of bismuth, Bi_2S_3, and sometimes copper and iron; a variety from Mexico contains about 8% antimony. Bismuthinite is orthorhombic although its thin needlelike crystals are rare as it usually occurs in foliated or fibrous masses. It has one good cleavage parallel to the prism; hardness, 2; specific gravity, 6.78; metallic luster; streak, lead gray; color, similar but often with iridescent tarnish; opaque.

Bismuthinite is a rather rare mineral although somewhat widely distributed. European localities are in Norway, Sweden, Saxony, Rumania, and England. It is found also in Bolivia, Australia, and in the United States in Utah. It is used as an ore of bismuth. Bismuthinite also is known as *bismuth glance*.

BISON. The phylogeny and taxonomy of the bison are described in the article on **Bovini**.

American Bison. The story of the American Bison, sometimes mistakenly called "buffalo," has been told innumerable times. They were slaughtered by the millions (estimated at 60 million) as people moved westward across America. Once near extinction, fortunately as the result of protection, the American western Plains Bison is staging a comeback. At one time, it is estimated that there were fewer than a thousand of the animals remaining. In addition to the western plains, the bison also was found in portions of the eastern United States from Lake Erie south to Georgia. The eastern form was fully extinguished by the early pioneers. The Wood Bison which is larger still exists in the wild form in northwestern Canada. See Fig. 1.

The American Bison is a large ox-like animal, weighing in excess of one ton when fully grown, has a large shaggy head, small curved horns, prefers roaming in large herds, stands about 6 feet (1.8 meters) high, and has humped shoulders and a small, distinguishing beard. See Fig. 1. The front legs and body of the bull are covered with rather shaggy, thick fur, but the hindquarters are fully absent of shag, giving the appearance that perhaps the rear half of his "dress" has been closely clipped.

The Plains Indians of North America depended on bison hunting until the conquest and colonization of the West by the European immigrants. The Indians considered the skin of a white bison to be sacred and worshipped it in their hunting cults as a fetish. A.B. Szalay stated some years ago, "All actions of the Indians, all their habits, concepts, conditions of life, views, their whole life was connected in the closest sense with the bison. To the dying Indian the shaman would say: 'You came from the buffalos on earth, now you go home to the animals, to your ancestors, and to four spirits. May your way be gentle.' There are no known peoples in world

Fig. 1. Bison. (*A.W. Winchester*.)

history which has ever been so intertwined with any animal to such an extent as the Indians with their bison."

In the early 1700s, prior to the "great kill," in North America, from Alaska along the east slopes of the Rocky Mountains southward to northeastern Mexico and across the continent almost to the Atlantic, millions of bison lived. They roamed over the grasslands in almost endless herds. The Indians' bow-and-arrow hunting did not diminish the giant herds, nor did severe winters, droughts, prairie fires, and other natural catastrophes to which many animals fell victim every year. In the autumn, bison migrated several hundred miles (km) south to spend the winter on better grazing grounds, and returned north in springtime. So-called "buffalo paths," stomped through the centuries, were sometimes used by settlers on their way west.

After the mass slaughter of the bison, it was not until 1889 that a group of naturalists and scientists, under the supervision of Dr. Hornaday of the New York Zoo, initiated a movement to save the bison from full extinction. In retrospect, this was considered a very close, last-minute move. This awakened the conscience of the American public, one of the first efforts of species conservation in North America. At that time it was estimated that the few remaining American bison were either in zoos or part of a herd of fewer than a thousand which were protected because they lived in Yellowstone National Park. Other preserves were established in Montana, Nebraska, and the Dakotas, and gradually the rugged animals increased in number. The Canadian government purchased an existing herd of about 700 bison from a private owner and transported them to Bison Park in Wainwright, Alberta, which was created especially for this purpose. From 1907 to 1920 the herd had increased to about 5000 head. Aside from any natural catastrophe, bison in North America no longer face full extinction.

The bison is not a harmless animal and will charge quickly when it is cornered and able to recognize its enemy. With its highly developed sense of smell, the bison is able to scent sources of danger at a distance of a few miles (km). Bison also have a keen sense for sources of water. In spite of their plump shapes, the bison move with amazing ease and endurance. They can travel over previously trampled paths at a fast pace. Longevity in bison, like most wild oxen, is 20 to 25 years.

European Bison. This animal is also large and impressive. The European bison is a close relative of the North American bison. Both species originated from *Bison sivalensis*, whose fossils have been found in northern India. It is postulated that a group of them migrated over the Himalayas, which were then still low, crossed the then existing land bridge northeast into North America, and evolved into the American bison; another group migrated westward and became the European bison. Each of these two groups developed into two different lines: a *steppe* type and a *forest* type. The steppe bison became extinct during the Glacial Period. The forest type bison, probably during the last Glacial Period, developed into an alpine and a plains form, of which the alpine form, the Caucasian bison, became extinct in 1927. However, the bloodline of this bison exists in varying degrees in the breeding groups of zoological gardens.

Once the habitat of the European bison reached across Europe and probably as far as Siberia. It was forced back not so much by severe hunting as by steadily expanding human settlements and the increasing clearance of the woodlands. The number of European bison decreased steadily with land cultivation in Europe. In the beginning of the nineteenth century, the remaining Plains bison had retreated into the forests of Bielowecza. There, in the heartland of Poland, southeast of Bialystok, 300 to 500 animals led a hidden existence. The number of this herd varied constantly, but, on the whole, the number of this herd steadily decreased, partly due to poaching and partly because of the overcrowding of the area. The turmoils of World War I brought utter ruin, and the final shot came in 1921 from a poacher.

Fortunately, before the herd ceased to exist, some of the bison (a total of 56 animals) had been given to zoos and private game reserves. Through relentless efforts, these animals were bred and in the late twentieth century numbered in the few thousands.

BISULFITE PROCESS. See **Pulp (Wood) Production and Processing**.

BIT (Data System). An abbreviation of *binary digit*. A single character in a binary numeral, i.e., a 1 or 0. A single pulse in a group of pulses also may be referred to as a bit. The bit is a unit of information capacity of a storage device. The capacity in bits is the logarithm to the base two of the number of possible states of the device.

Parity bit. A check bit that indicates whether the total number of binary "1" digits in a character or word (excluding the parity bit) is odd or even. If a "1" parity bit indicates an odd number of "1" digits, then a "0" bit indicates an even number of them. If the total number of "1" bits, including the parity bit, is always even, the system is called an even parity system. In an odd parity system, the total number of "1" bits, including the parity bit, is always odd.

Zone bit. (1) One of the two leftmost bits in a system in which six bits are used for each character. Related to overpunch. (2) Any bit in a group of bit positions that are used to indicate a specific class of items; e.g., numbers, letters, special signs, and commands.

BITTERLING *(Osteichthyes).* Fishes of the general group *Cypriniformes*, which also embraces other minnows, and also suckers, loaches, and hillstream fishes. The various species are thus allied to the carp. One species, *Rhodeus amarus*, lives in European waters and the others inhabit Eastern Asian waters. The Central European bitterling (*Rhodeus*

sericeus amarus) is deep-bodied, attaining a length of about $3\frac{1}{2}$ inches (9 centimeters). This species displays an interesting and unusual reproductive habit, namely, that of the female developing a long ovipositor which permits deposition of the eggs into the mantle cavity of a fresh water clam or mussel. Thus, within the living clam, the eggs incubate and hatch. A related species in Japan (*Acheilognathus lanceolata*) displays similar habits.

BITTERN *(Aves, Ciconiiformes)*. Wading birds allied to the herons and egrets. They have moderately long legs and a straight beak that is strong and sharp. Two species, the American, *Botaurus lentiginosus*, and least, *Ixobrychus exilis*, bitterns, occur in North America, and several others are found on other continents.

The *Botaurus lentiginosus* ranges from the Gulf of Mexico north and west to Manitoba. The bittern is found in marshy areas where there is ample vegetation for good concealment. The bird is most active at night. Freezing in position when approached, the bird holds its head high, completely still, taking advantage of the manner in which its plumage and coloring match numerous natural backgrounds. The birds are easy to lose from view.

The bittern has a booming type of cry. It is stocky and is often seen pointing its bill upward. The color is light brown over the body with white trimming. The head is solid brown and legs are gray. Length is about 23 inches (58 centimeters); width about 35 inches (89 centimeters) with wing spread. The bittern feeds on small animals and insects found near watery areas. The neck may take the form of an S-shape when retracted for flight. The long neck enables the bill to act as a spear when spotting food. The claws have comb-like serrations that are used, along with the bill, for crumbling some of the down feathers of its chest into a fine white powder which, in turn, is used for preening its feathers. This procedure is used particularly when feathered areas on the body have been soiled by fish slime. The down soaks up the slime or oil and the claws comb it out. The heron and egret also possess powder downs.

The smallest of the species is the least bittern. It possesses a rich brown plumage with white trimming, but is a weak flier. Length is about 11 inches (30 centimeters), spread is about 17 inches (43 centimeters). Bitterns are mentioned in the Scriptures. See also **Ciconiiformes**.

BITTER PATTERNS. A method for detecting domain boundaries at the surface of ferromagnetic crystals. If a drop of a colloidal suspension of ferromagnetic particles is placed on the surface of the crystals, the particles will collect along the domain boundaries where the field is strongest.

BITUMEN. Natural flammable substances of a wide range of color, hardness, and volatility, constituted mainly of a mixture of hydrocarbons and essentially free from oxygenated bodies. Petroleums, asphalts, natural mineral waxes, and asphaltites are considered bitumens.

BIVALVE. A shell composed of two distinct parts or valves. Such shells are secreted by brachiopods, in which the valves are dorsal and ventral, and by certain crustaceans (*Ostracoda*) and mollusks (*Pelecypoda*) in which the valves are lateral. The most common examples of bivalves are among the edible mollusks, including clams, oysters, and scallops. Bivalves of commercial significance are described in the entry on **Mollusks**.

BIVANE. (Or bidirectional wind vane.) A sensitive wind vane used in turbulence studies to obtain a record of the horizontal and vertical inclinations of the wind vector. The instrument consists of two lightweight airfoil sections mounted orthogonally on the end of a counterbalanced rod that is free to rotate in the horizontal and vertical planes. The angular positions of the vane are commonly detected by potentiometers. Some bivanes have a propeller on the end opposite the airfoils to enable measurement of the total wind speed.

BJERKNES, VILHELM FRIMANN KOREN (1862–1951). Vilhelm Bjerknes is considered by many to be one of the founders of modern meteorology and weather forecasting. As a young boy, Bjerknes assisted his father, Carl Bjerknes (a professor of mathematics at the University of Christiania, Norway), in carrying out experiments to verify the theoretical predictions that resulted from his father's hydrodynamic research. He continued this collaboration during his undergraduate studies at the University of Kristiania in 1880 (the city was renamed Kristiania in 1877).

After studying mathematics and physics, Bjerknes received his Master's Degree from Kristiania in 1888. During this time, he decided to cut all collaborative ties with his father, as he showed an increasing tendency toward professional isolation and a fear of publishing the results of his research. Young Vilhelm believed that continuing work with his father would be detrimental to his career, a tough decision for a son who was devoted to his father.

Soon after graduation, Bjerknes was awarded a state scholarship that enabled him to continue his studies abroad. Arriving in Paris in 1889, he attended lectures on electrodynamics given by Jules Henri Poincare. Then, in 1890, he moved to Bonn, Germany, and became an assistant to, and eventually a scientific collaborator with, the German physicist Heinrich Hertz. Together, Hertz and Bjerknes conducted a comprehensive study of electrical resonance (an effect in which the resistance to the flow of an electrical current becomes very small over a narrow frequency range) that was influential in the development of radio. In 1892, Bjerknes returned to Norway and completed his doctoral thesis on the work that he did in Bonn.

After two years as a lecturer at the Hogskola (School of Engineering) in Stockholm, Bjerknes became a professor of applied mechanics and mathematical physics at the University of Stockholm in 1895. Two years later he discovered the circulation theorems that led him to a synthesis of hydrodynamics and thermodynamics applicable to large-scale motions in the atmosphere and oceans. He then began devising a research plan that would use these theorems to compute the future state of the atmosphere given its present (initial) condition. This work ultimately resulted in the theory of air masses and fronts. As a primary piece of the modern weather forecasting puzzle, this theory described the life cycle of mid-latitude weather systems (low pressure systems).

On November 2, 1897, Bjerknes' son Jacob was born. Jacob would later collaborate with his father and become a famous meteorologist in his own right. Jacob discovered the mechanism that controls the behavior of mid-latitude cyclones.

In a programmatic paper published in 1904, Bjerknes proposed the procedure now known as numerical weather prediction. He suggested that weather prognosis (forecasting) should be considered as an initial value problem of mathematical physics, and could be carried out by integrating the governing equations forward in time, starting from the observed, initial state of the atmosphere. In short, Bjerknes discovered that with enough information about the current state of the atmosphere, scientists can use math formulas to predict future weather patterns. Unfortunately, due to the lack of processing facilities (computers), the calculations he envisioned were not feasible at that time. Nevertheless, Bjerknes considered weather forecasting as the principal objective of meteorological research, trusting that adequate observations and computer facilities would emerge in the future.

In 1905, during a trip to the United States, Bjerknes presented his research on the theory of how air masses move and explained his plans to apply mathematics to weather forecasting. The Carnegie Institution was so impressed they awarded him a grant to pursue his research interests. He would continue to receive their support until 1941.

After chairing the Department of Applied Mechanics and Mathematical Physics at the University of Kristiania for five years, Bjerknes accepted the chair of geophysics at the University of Leipzig (Germany), and the directorship of the new Leipzig Geophysical Institute in 1912. He was joined by many of his Kristiania colleagues, as well as his son Jacob, who also became a collaborator during his time at Leipzig. Together, father and son established a network of weather observing stations in Norway. The data gathered from these stations would eventually lead to the development of their theory of polar fronts.

In 1917, Bjerknes accepted a position with the museum in Bergen (Norway; now part of the University of Bergen), where he founded the Bergen Geophysical Institute. Bjerknes was 55 years old at the time and most historians agree this is when Bjerknes did his best work, continuing his research into the mathematical approach to weather

forecasting. Working with his son Jacob and Jacob's fellow student, Halvor Solberg, they were later joined by the Swedish meteorologist Tor Bergeron. Together, this extraordinary group of meteorologists put forward the theory that weather activity is concentrated in relatively narrow zones, which form the boundaries between warm and cold air masses. They called these zones "fronts, "an analogy with the First World War battlefronts. The theory was widely acclaimed and became known as the "polar front theory of a developing wave cyclone "or, simply, the "polar front theory. "See also **Fronts and Storms**. What these scientists gave to the world was a working model of how a mid-latitude cyclone progresses through the stages of birth, growth, and decay. Their model marked a turning point in atmospheric science. See Fig. 1.

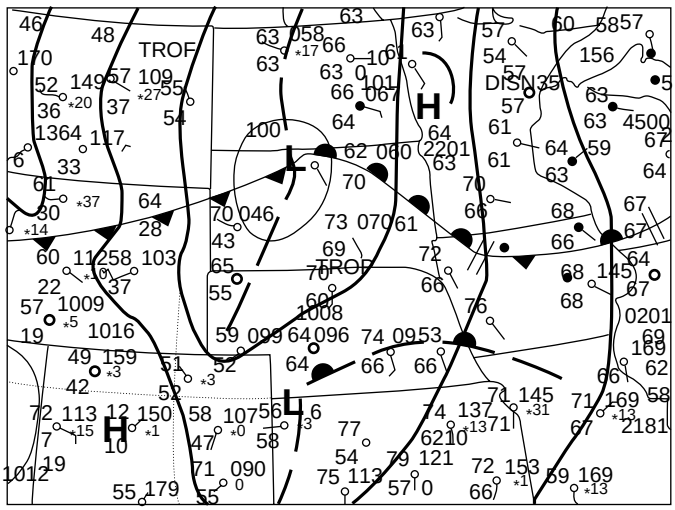

Fig. 1. Bjerknes, in collaboration with his son Jacob and other scientists at the Bergen School in Norway, developed the polar front theory. This theory is the basis for much of current weather forecasting, and described the interaction of warm and cold air masses. Warm fronts are marked by half circles, and cold fronts by triangles. Map courtesy of the National Weather Service.

While at the Institute, in 1921, Bjerknes published "On the Dynamics of the Circular Vortex with Applications to the Atmosphere and to Atmospheric Vortex and Wave Motion. "Now considered a classic, this work offered one of the first modern and extensive accounts of the structure and evolution of cyclones. This work remarkably remains unaltered to this day. Bjerknes made his final move in 1926 when he accepted the chair of the Department of Applied Mechanics and Mathematical Physics at the University of Oslo (Kristiania was renamed Oslo in 1925). There, in addition to his meteorological studies, he continued to study the hydrodynamical work started by his father. In 1926, he also produced the theory that sunspots are the erupting ends of magnetic vortices broken by the different rotation rates of the sun's poles (slower rotation) and equator (faster rotation).

BLACKBIRD *(Aves, Passeriformes).* A term variously applied to different species of birds. The term sometimes is used to describe the ouzel of Europe. Several species of North American birds of the genus *Agelaius*, related to the orioles and grackles, may be called blackbirds. In the West Indies, the name is applied to the ani, a member of the order of Cuculiformes. In England, the blackbird is called the thrush (*Turdus merula*).

In the United States, Brewer's blackbird is found in the meadows and prairies of the western states and ranges eastward to about the Mississippi River and southward into Central America. The bird, from 8 to 9 inches in length (20 to 23 centimeters), appears much like a short-tailed grackle. See **Grackle**. The bird has a white eye (male). Females have dark eyes. At a distance, the bird appears all-black. Close up, purplish and greenish iridescence is noticeable. The rusty blackbird is quite similar, but prefers woodlands and swamps, whereas the Brewer's blackbird likes barnyards and fields. The song of these birds is a hoarse whistle. The redwinged blackbird (*Agelaius phoeniceus*) is quite similar with exception of red coloration on its throat and shoulders. Blackbirds tend to fly in flocks. These birds feed principally on grain. They are known for robbing the nests of other birds.

Redwing is also a term applied to a European thrush, *Turdus musicus*.

BLACK BODY. This term denotes an ideal body which would, if it existed, absorb all and reflect none of the radiation falling upon it; its reflectivity would be zero and its absorptivity would be 100%. Such a body would, when illuminated, appear perfectly black, and would be invisible except its outline might be revealed by the obscuring of objects beyond. The chief interest attached to such a body lies in the character of the radiation emitted by it when heated and the laws that govern the relations of the flux density and the spectral energy distribution of that radiation with varying temperature.

The total emission of radiant energy from a black body takes place at a rate expressed by the Stefan-Boltzmann (fourth-power) law; while its spectral energy distribution is described by Wien's laws, or more accurately by Planck's equation, as well as by a number of other empirical laws and formulas. See also **Emissivity**; and **Thermal Radiation**.

The nearest approach to the ideal black body, experimentally, is not a sooty surface, as might be supposed, but an almost completely closed cavity in an opaque body, such as a jug. The laboratory type is usually a somewhat elongated, hollow metal cylinder, blackened inside, and completely closed except for a narrow slit in one end. When such an enclosure is heated, the radiation escaping through the opening closely resembles the ideal black-body radiation; light or other radiation entering by the opening is almost completely trapped by multiple reflection from the walls, so that the opening usually appears intensely black. See also **Planck Radiation Formula**.

BLACK BOX. 1. In engineering design, a unit whose output is a specified function of the input, but for which the method of converting input to output is not necessarily specified.

2. Colloquially, any unit, usually an electronic device such as an amplifier, which can be mounted in, or removed from, a rocket, spacecraft, or the like as a single package.

BLACKFISH *(Osteichthyes).* (1) The black sea bass, *Centropristis striatus*. See also **Bass (Osteichthyes)**. (2) The Alaskan blackfish (*Dallia pectoralis*), the only representative of the family inhabiting streams and ponds of Alaska and Siberia. Chief food of natives of some parts of North Alaska. (3) A marine fish (*Centrolopus niger*) of the family *Stromateidae*.

BLACK-FLY *(Insecta, Diptera).* A minute fly whose small head and large thorax give it a hump-backed appearance. They are also called buffalo gnats and the Indian name no-see-'em is sometimes used for the very small species. They constitute the family *Simuliidae*. Its distribution is worldwide, the larvae being attached by anal extremity to rocks in running water.

While some of these insects are harmless, others are among the most troublesome of our blood-sucking insects. Their bite is extremely irritating, considering its size, and the swarms are sometimes so numerous that their attack is serious to humans and may cause the death of smaller animals, such as chicks. Certain species like *Simulum damnosum* (Theobald) of Africa transmit to humans the filaria *Onchocera volvulus* (Leuckart)

causing the subcutaneous disease onchoceriasis — "river-blindness." They are especially abundant in the woods, where campers and outdoor workers sometimes find it necessary to use special preparations on exposed portions of the skin to prevent attack.

BLACK FOG. See **Fog and Fog Clearing**.

BLACK FROST. 1. A dry freeze with respect to its effects upon vegetation, that is, the internal freezing of vegetation unaccompanied by the protective formation of hoarfrost. A black frost is always a killing frost, and its name derives from the resulting blackened appearance of affected vegetation.

2. Among some fishermen, a steam fog that extends above the bridge level of the fishing boats. If the steam fog does not reach this height, it is a white frost.

See also **Precipitation and Hydrometeors**.

BLACK HOLE. By definition, a black hole is a body that has become, by whatever mechanism, sufficiently compact that the escape velocity from its "surface" exceeds the speed of light. First hypothesized by Laplace in 1799, black holes were predicted by the general theory of relatively, as a consequence of the distortion of the gravitational field around a massive body, from the simple Newtonian inverse square law. This condition is believed to be the final state of a star, which is more massive than the upper limit for a neutron star and hence incapable of reaching hydrostatic equilibrium when its nuclear fuel has been exhausted. Under such conditions, first shown by Oppenheimer and Snyder, the collapse of the core will pass through the critical radius, which is given by:

$$R_* = 2GM/c^2$$

where G is the gravitational constant, c is the speed of light, and M is the mass. For the sun, this is of the order of 1.5 kilometers. The last stable orbit is at $3R_*$ for particles. Within this region, there is no escape — any signal will simply be directed down the hole. An observer at a large distance will, however, see progressive deceleration (a relativistic effect) of the in-falling matter as the particles approach the speed of light. Once within this radius, nothing can prevent the collapse from continuing.

A famous theorem due to Israel and elaborated on by Hawking, Penrose, and Carter, the so-called "No Hair theorem," states that the only attributes which can be used to distinguish one black hole from another are mass, angular momentum, and charge. The Schwarzschild solution (found by K. Schwarzschild soon after Einstein's first paper on gravitation), was the first to demonstrate the existence of this singularity or event horizon and involved a point, non-rotating mass with no charge. The rotating case was not solved exactly until 1963 when Kerr showed that rotation introduces a second horizon, inside of which the inertial frame is dragged around with the hole. From this region, it is possible for the particle to escape from the hole and appear at infinity with some extra energy, extracted from the hole (the Penrose process).

Should the stellar collapse occur in a binary system, it may become possible for the external observer to surmise the existence of the hole by optical and x-ray observation. If mass flows from an oversized companion, and accretes onto the hole (either from a wind or forming an accretion disk) the rapid motion in the vicinity of the event horizon can raise the temperature of the matter to greater than 10^7 Kelvin. At this temperature, x-rays will be emitted with a characteristic spectrum and flickering rate. Since the mass of the emitting object can, in principle, also be obtained from its orbital motion (See **Binary Stars**), it is possible to choose between a neutron star and black hole as the responsible accreter; if the mass is greater than about three solar masses, it is likely a black hole.

At this writing, several binary systems seem to require the presence of a black hole. Cygnus X-1, also known as HDE 226868, is especially well studied and appears the best galactic case. This star is a strong x-ray source, with a high-temperature spectrum and millisecond flickering. Bolton finds that it consists of a massive O star primary and a secondary, which must be at least 16 solar masses. Attempts to explain the light curve and radial velocity variations by evoking a multiple system have so far failed to meet fairly strict observational criteria. In consequence, it is likely a firm conclusion that in this system at least we are observing a fairly low mass black hole with an age of a few million years.

LMC X-3, a binary in the large Magellanic Cloud, has a B main sequence star and an x-ray emitting companion which seems too massive for a neutron star. The peculiar binary SS433 = V1343Agl may have a black hole at the center of its jet-producing accretion disk. AO620 is a third galactic object with a probable black hole, in this case as the more massive star in the binary.

The active galaxies, like *quasars*, Seyferts, and BL Lacertae galaxies, also appear to require massive (at least 10^7 solar masses) black holes in their nuclei in order to account for the x-ray, optical, and radio emissions and energies observed. There is also weak evidence that our galaxy may have a massive, but not rapidly accreting, black hole of perhaps a few million solar masses at its center. It would seem then that stellar collapse, following supernova explosions and stellar coalescence, may form massive black holes in a wide variety of galaxies, and that their presence is far more ubiquitous than might have been initially expected. See also **Quasars**.

In a merger of quantum mechanics and relativity, Hawking has shown that particle creation near the event horizon can led to a process known as "black hole evaporation." This process gives a lifetime for the hole that varies as M^{-3}, normally far too long for stellar mass holes to be important, but which is of order 10^{10} years for $M \sim 10^{15}$ g. Such objects could be relics of the early universe, and could contribute to the microwave background in the early stages of the expansion.

The full and rich picture of the structure, evolution, and interaction of these objects, however, continues to be painted. See Hubble Space Telescope.

BLACKHORSE *(Osteichthyes)*. A fish (*Cycleptus elongatus*) of the Mississippi River system; also called the Missouri sucker. It attains a length of 30 inches (76 centimeters) and its flesh is excellent.

BLACK ICE. 1. Thin, new ice on freshwater or saltwater, appearing dark in color because of its transparency, which is a result of its columnar grain structure. On lakes, black ice is commonly overlain by white ice formed from refrozen snow or slush.

2. A mariner's term for a dreaded form of icing sometimes sufficiently heavy to capsize a small ship.

3. A popular alternative for glaze. A thin sheet of ice, relatively dark in appearance, may form when light rain or drizzle falls on a road surface that is at a temperature below 0 °C (32 °F). It may also be formed when supercooled fog droplets are intercepted by buildings, fences, and vegetation. See also **Ice**.

BLACK, JAMES WHYTE (1924–). Black was born in Uddington, Scotland, the son of a coal miner who later became an engineer. At 15, he was awarded a scholarship to study medicine at St Andrew's University. After gaining his degree in 1946, he became senior lecturer in physiology at the University of Malaya. In 1950, he returned to Scotland to lecture in physiology at Glasgow Veterinary School. It was there that he began his research on the increase of gastric secretions caused by histamine. He also became acquainted with the beta-adrenoceptors, discovered in 1948 by the American pharmacologist Raymond Ahlquist, who suggested that adrenaline (epinephrine) and noradrenaline (norepinephrine) stimulate the heart via these receptors. Black conceived the idea of a beta-adrenoceptor antagonist to treat angina pectoris. This is a painful disease, caused by an increased heart rate, which leads to insufficient oxygenation of the heart. Black thought that the answer to the problem might lie in reducing the demand for oxygen, and that this might be achieved by blocking the receptors responsible for the increased heart rate. See also **Adrenaline and Noradrenaline**; and **Histamine**.

Black approached ICI with his project. As a result, in 1958 he was offered the directorship of pharmacological research at ICI's pharmaceutical division, where he developed pronethalol, the first effective beta-receptor antagonist. However, it was found to cause tumors in mice, and Black went on to synthesize propranolol. Clinical investigation by Brian Prichard suggested it could be used for treating not only angina, but also hypertension. Marketed under the name Inderal, propranolol was to revolutionize the treatment of hypertension. See also **Hypertension**.

In contrast to the mass screening methods then commonly used by the pharmaceutical industry, Black's approach relied on a deep understanding of biological processes, on drugs that mimicked naturally occurring substances, and on appropriate tests ("bioassays") to study their action *in vitro*. It was this novel approach that enabled him to develop drugs that blocked the receptors involved in angina pectoris and hypertension, and led to an important new class of drugs, the so-called "beta blockers." See also **Drug Discovery (The History)**.

In 1964, Black moved to the British subsidiary of Smith Kline and French, where he sought a chemical that would block the H_2 histamine receptor, which by a systematic study he showed to be involved in excess gastric secretions. After thousands of compounds had been tested, in 1972 a likely candidate was identified in guanylhistamine. However, the serious side effects brought out by the clinical trials prompted Black to modify the molecule, and develop a superior anti-ulcer drug: cimetidine (better known as Tagamet).

In 1973, Black became head of pharmacology at University College London, where he remained four years, before accepting the post of director of therapeutic research at the Wellcome Research Laboratories. In 1984, lured back into academia, he joined King's College of Medicine and Dentistry.

Black's contribution has been recognized by several honors and awards. He was elected Fellow of the Royal Society in 1976 and knighted in 1981. In 1988 he was awarded jointly with two American pharmacologists, George Hitchings and Gertrude Elion, the Nobel Prize for Physiology or Medicine. Although it was unusual for pharmacologists to receive it, the Prize recognized the important contribution their rational approach to drug design had made to medicine. See also **Hitchings, George Herbert (1905–1998)**; and **Elion, Gertrude Belle (1918–1999)**.

VIVIANE QUIRKE, The Royal Institution of Great Britain, London, UK

BLACK, JOSEPH (1728–1799). Joseph Black was a close friend of the geologist James Hutton and the economist Adam Smith with whom he shared a central role in the Scottish Enlightenment. Born in France the son of an Ulsterman and his Scottish wife, he was educated in Belfast but went to Glasgow University at the age of 16. He completed his arts course in 1748 and began to study medicine not through a determination to be a physician, but through the desire to study natural philosophy under a new lecturer in chemistry — William Cullen (1710–1790) who was one of the first teachers in Britain to base his teaching on principles of chemistry rather than on *materia medica*.

After four years in Glasgow, Black moved to Edinburgh to complete his studies, choosing the subject of causticity and the character of the alkaline magnesia alba (magnesium carbonate) — commonly used for acidic indigestion — as the topic for his MD dissertation. He engaged in painstaking and meticulous experimental research, which he extended to quicklime and potash and presented to the Philosophical Society of Edinburgh in an essay entitled "Experiments on magnesia alba, quicklime and other alcaline substances" in 1755.

Black attempted to show that "fixed air" (carbon dioxide) was lost when magnesia was heated, but given the practical difficulties of collecting the "fixed air," he used a series of chemical reactions to prove his arguments. In the process he not only promoted reactivity as a reliable indicator of chemical change and a principal chemical methodology, he also noted that quicklime only absorbed one sort of air — "fixed air" — but did not absorb the rest of the air, thereby indicating that there were at least two sorts of air. This information was critical to later chemical research.

Black was appointed to William Cullen's position in Glasgow in 1755 and changed the direction of his researches to explore the nature of heat — then regarded by most chemists of the period as a substance. Black was extremely reluctant to hypothesize and he deplored most forms of speculation and theorizing entirely. It was this reluctance, consistent with contemporary Enlightenment philosophy and his insistence on the facts, which helped him develop important scientific insights into the way substances — notably water — absorb heat. Black was interested in the phenomenon of melting and in the way that some salts dissolved in water cause temperature changes by either increasing or decreasing the temperature of water. He considered the question of why ice does not melt immediately when the temperature rises above freezing and how it was possible to measure changes using a mercury thermometer when no change of state occurred. His researches led him to develop the idea of latent heat, which is the extra heat required to melt the ice, and thereby calculate the latent heat of ice. See also **Latent Heat**.

Black began to work on the related issue of the heat of vaporization from 1762 and was able to calculate the latent heat of steam and to show that the conversion of steam to water and vice versa was probably equal and opposite. His work in this area brought science and technology in partnership as he had to work in close collaboration with the pioneer of steam power, James Watt, who was instrument maker to the University of Glasgow. Black developed his research to discover the specific heat of different substances — the fact that different substances took up heat at different rates — and developed an understanding of the absorption of heat as a chemical process and a function of chemical composition rather than bulk or density.

Black took up the Edinburgh chemistry chair in 1766 but did little active research. He had to devote most of his efforts to teaching and to his small private medical practice. He became an influential adviser to industry, for instance suggesting that caustic potash (potassium hydroxide) could act as a bleach for linen.

Black's work on latent heat provided the foundation for Lavoisier's caloric theory of heat and Black himself embraced Lavoisier's chemistry from the 1790s when many, particularly in English universities and research institutions, preferred Joseph Priestley's phlogiston theories. He was elected a foreign member of the French Academy of Sciences in 1789.

BLACKOUT. 1. A fadeout of radio communications due to ionospheric disturbances. Blackouts are most common in, but are not restricted to, the arctic. An arctic blackout may last for days or even weeks during periods of intense auroral activity. Past experiments with high-altitude nuclear detonations have produced blackouts and artificial auroras over the subtropics.

2. A fadeout of radio and telemetry transmission between ground stations and vehicles traveling at high speeds in the atmosphere caused by signal attenuation in passing through ionized boundary layer (plasma sheath) and shock wave regions generated by the vehicle.

3. A vacuum tube characteristic, that results from the formation of a dielectric film on the surface of the control grid. A negative charge, accumulated on the film when the grid is driven positive with respect to the cathode, affects the operating characteristics of the tube.

4. A condition in which vision is temporarily obscured by a blackness, accompanied by a dullness of certain of the other senses, brought on by decreased blood pressure in the eye and a consequent lack of oxygen, as may occur, e.g., in pulling out of a high-speed dive in an airplane.

BLACK SMOKER. A chimney-like structure on the seafloor made of metal sulfides, out of which hot ~350 °C (~662 °F) fluids that look like black smoke flow. The black color of the fluid is due to mineral particles within it. Generally hundreds of meters (feet) wide, vent fields are formed when superheated water from below the Earth's crust comes through the ocean floor. The superheated water is rich in dissolved minerals from the crust, most notably sulfides, which crystallize to create a chimney-like structure around each vent. When the superheated water in the vent comes in contact with the frigid ocean water, many minerals are precipitated, creating the distinctive black color. The metal sulfides that are deposited can become massive sulfide ore deposits in time.

Black smokers were first discovered in 1977 around the Galápagos Islands by the National Oceanic and Atmospheric Administration. They were observed using a small submersible vehicle called Alvin. Today, black smokers are known to exist in the Atlantic and Pacific Oceans, at an average depth of 2,100 meters (6,889 feet).

Although life is very sparse at these depths, black smokers are the center of entire ecosystems (See Fig. 1). Sunlight is nonexistent, so many organisms — such as archaea and extremophiles — must convert the heat, methane [CAS: 74-82-8], and sulfur compounds provided by black smokers into energy through a process called *chemosynthesis*. In turn, more complex life forms like clams and tubeworms feed on these organisms. The organisms at the base of the food chain also deposit minerals into the base of the black smoker, thus completing the life cycle. See also **Chemosynthesis**.

A bacterium that uses photosynthesis has been found living near a black smoker off the coast of Mexico. At a depth of 2,500 meters (8,202 feet), no sunlight penetrates the waters. Instead, the bacterium, part of the Green sulfur bacteria family, use the faint glow from the black smoker for photosynthesis making it the first organism found in nature to use a light other than sunlight for the process (Beatty, *et al.*).

New and unusual species are constantly being discovered in the neighborhood of black smokers: for instance, the Pompeii worm in the 1980s, and, in 2001, during an expedition to Indian Ocean's Kairei hydrothermal vent field, an armor-plated gastropod. The latter uses iron sulfides (pyrite [CAS: 1309-36-0] and greigite $Fe^{2+}Fe_2{}^{3+}S_4$) for the structure of its dermal *sclerites* (hardened body parts), instead of calcium carbonate [CAS: 471-34-1]. The extreme pressure of 2,500 meters (8,202 feet) of water (approximately 24.5 megapascals) is thought to play a role in stabilizing iron sulfide for biological purposes. This armor plating probably serves as a defense against the venomous *radula* (teeth) of predatory snails, co-existing in the same community. This snail, which is unique in its kind, has not yet been named to date.

TABLE 1. RECORD BLADDERNUT TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
American bladdernut (1966) (*Staphylea trifolia*)	19	48.3	36	11	37	11.3	Michigan
Sierra bladdernut (1986) (*Staphylea balanderi*)	14	35.6	28	8.53	12	3.66	California

[1]From American Forests (with permission).
[2]At 4.5 feet (1.4 meters).

BLADDERNUT TREE OR SHRUB. Of the family Staphyleaceae (bladdernut family), the American bladdernut (*Staphylea trifolia*) is a rather slender tree or shrub, ranging from 6 to 12 feet (1.8 to 3.6 meters) in height and is rarely found as a tree (up to 25 feet; 7.5 meters). The plant has compound leaves of deep green color. The flowers are small and white. Possibly the most notable feature of the plant is the large, inflated, three-sided pods of light-brown color, 2 inches (5 centimeters) in length, and containing from one to four seeds. The seeds rattle inside the capsule when shaken. The plant is found from western Quebec westward into Ontario and Minnesota and southward to the latitude of South Carolina.

Record bladdernuts as reported by American Forests are listed in Table 1.

BLADDER (Urinary). See **Kidney and Urinary Tract**.

BLADDER WORM *(Platyhelminthes, Cestoda).* An immature resting stage of tapeworms consisting of a bladder-like cyst in which one or more heads are inverted. Also known as the cysticercus stage.

BLAGDEN LAW. The depression of the freezing point of a solution is, for small concentrations, proportional to the concentration of the dissolved substance.

BLASTOCOELE. The first cavity formed during the embryonic development of animals. In many species the cleavage of the fertilized ovum gives rise to a hollow blastula of spheroid form; the cavity of this structure is the blastocoele.

BLASTOMERE. Any of the cells resulting from the subdivision of the fertilized ovum during early embryonic development.

BLASTOMYCOSIS. A systemic fungus (mycotic) disease caused by the dimorphic fungus *Blastomyces dermatitidis*. The disease is found in certain parts of the Americas and in numerous areas in Africa. The disease is endemic in the southeastern and south central portions of the United States. The disease also has extended northward in several pockets along the Mississippi and Ohio Rivers and on into central Canada. In South America, the disease is caused by Blastomyces brasiliensis. Although the disease may affect persons of nearly any age, most of those afflicted are between 20 and 50 years of age. Incidence in males is six times that for females. Persons who work outside or who vacation often in areas with soils that may contain the soil sporophyte run a higher risk of becoming infected.

Blastomycosis manifests itself as a pulmonary disease with symptoms closely resembling those of tuberculosis, coccidioidomycosis, and histoplasmosis. The disease also takes a cutaneous form, but skin lesions appear to be due to metastatic infection from the primary site. The characteristic lesion in cutaneous blastomycosis is raised, verrucous, and crusted with a serpiginous border, and is usually seen on the face and upper extremities. Minimal erythema exists, and unless bacterial infection is superimposed the lesions are neither painful nor pruritic. The initial portal of entry is the respiratory tract. As the result of inhalation, the fungus spores are deposited in the peripheral air spaces of the lower lobes of the lung. Often minor infections will be quickly eradicated without detectable traces of the infection. But, in a certain percentage of cases, the infection may take a more serious route and this may range from mild pulmonary disease all the way to lung destruction and cavity formation. Metastatic spread also may include, in addition to the skin, the skeletal system, and genitalia. There have been a few reports of venereal transmission of *B. dermatitidis* from men with prostatic infection to their sexual partners. Less frequently, the rectum and the heart may be infected. Between 50 and 79% of patients with chronic blastomycosis have simultaneous multiple organ system infection.

Diagnosis is made by growing organisms, from sputum, cutaneous lesions, etc., on the surface of Sabourand's agar slants (incubated at 30 °C for 1 month). The pathological hallmark is a mixed and acute inflammation and the organisms require demonstration on histological section. Treatment is with one of two antimicrobial agents, amphotericin B or hydroxystilbamidine isethionate. The former is usually used for patients with advanced, progressing disease, particularly when several organs may be involved. The latter is more frequently used for patients with chronic dermatological disease. This is usually considered second-line therapy. Relapses may occur within a period of up to 9 years after a course of treatment.

Often acute blastomycosis will run its course without therapy, but persons who have not shown improvement within 2 weeks should be treated. In more severe, less frequent cases, where host defenses are impaired, surgery may be indicated in the case of persistent pulmonary cavities and deforming orthopedic lesions that may accompany chronic infection. See also **Bacterial Diseases**.

BLASTULA. The stage in embryonic development that results from cleavage of the fertilized ovum and precedes the establishment of the germ layers. It is a hollow sphere in its primitive form but is modified in many animals, particularly in connection with the extensive storage of yolk in the egg, and in some of these modified forms the exact equivalent of the primitive blastula is difficult to determine.

BLEACHING AGENTS. A bleaching agent is a material that lightens or whitens a substrate through chemical reaction. The bleaching reactions usually involve oxidative or reductive processes that degrade color systems. These processes may involve the destruction or modification of chromophoric groups in the substrate as well as the degradation of color bodies into smaller, more soluble units that are more easily removed in the bleaching process. The most common bleaching agents generally fall into two categories: chlorine and its related compounds (such as sodium hypochlorite) and the peroxygen bleaching agents, such as hydrogen peroxide and sodium perborate. Reducing bleaches represent another category. Bleaching agents are used for textile, paper, and pulp bleaching as well as for home laundering.

History of Bleaching

Textile Bleaching. There is evidence of chemical bleaching of cloth prior to 300 BC. Soda ash prepared from the burning of seaweed was used to clean the cloth followed by souring, ie, treatment with soured milk to neutralize the alkalinity remaining on the cloth. The cloth was then exposed to the sun to complete the bleaching process. Sun bleaching, which became known as crofting, occurred over a matter of weeks during which time the cloth was kept moist to enhance the bleaching process. During the eighteenth century, improvements were developed including the use of sulfuric acid in the souring process and the use of lime in the cleaning process, though crofting still required large tracts of primarily

coastal land. With the onset of mechanized weaving, the production of cloth was outstripping the availability of land, which set the stage for the introduction of chemical bleaching.

Scheele, a Swedish chemist, discovered chlorine gas in 1784 and demonstrated its use in decolorizing vegetable dyes. See also **Scheele, C. W. (1742–1786)**. Berthollet first produced solutions of hypochlorite by combining chlorine gas with alkalies and suggested using the gas for bleaching. A Scottish bleacher followed the suggestion and introduced chlorine into a bleach works in Glasgow. The efficiency of the process lead to its widespread use, though the low pH resulted in fabric damage and worker health problems. Two chemists, Valette and Tennant, developed chlorinated lime solutions that minimized these difficulties.

Tennant received a patent in 1799 for bleaching powder formed by the absorption of chlorine gas by dry hydrate of lime. Although this eliminated the need for on-site manufacture of chlorine, evidence suggests its use by bleachers caught on slowly. The bleaching powder was the chief source of textile bleaches over the next century and was the impetus for much of the early chemical and chemical engineering developments. Tropical bleach was developed by the addition of quicklime to bleaching powder to make a material suitable for use under tropical conditions. After World War I, technology for shipping liquid chlorine and caustic economically was developed allowing for the on-site manufacture of sodium hypochlorite solutions at the textile mills. As a result, use of bleaching powder diminished.

After World War I, other chlorine-based bleaches were developed. In 1921, the use of chlorine dioxide for bleaching fibers was reported followed by the development of the commercial process for large-scale production of sodium chlorite. In 1928, the first dry calcium hypochlorite containing 70% available chlorine was produced in the United States. This material largely replaced bleaching powder as a commercial bleaching agent.

Although hydrogen peroxide was prepared as early as 1818 by Thenard, the peroxides received little use as textile bleaches. Hydrogen peroxide was first prepared by the action of dilute sulfuric acid on barium peroxide, but later sodium peroxide and dilute acids were used. The prices of peroxides were high initially, and they found use only as a specialty chemical. Electrolytic methods in the 1920s allowed for the synthesis of less costly, strong (sim30%) solutions of hydrogen peroxide. By 1930, hydrogen peroxide was being used to bleach cotton goods, wool, and silk on a limited scale. Shortly thereafter, the J-Box was developed by the FMC Corp. allowing for continuous bleaching of textiles with hydrogen peroxide. By 1940, 65% of all cotton bleaching was done with hydrogen peroxide.

Plup Bleaching. The development of pulp bleaching parallels textile bleaching in many respects partially because early paper was generally made from rags. In the 1700s, sunlight was used to bleach paper. After the turn of the century, bleaching powder was used to whiten the rags used to make paper. During the nineteenth century, wood began to be used as a source of paper and sulfite pulping was developed. Although the Kraft process was discovered not long after, the sulfite process dominated for many years, since it yielded a whiter more easily bleached pulp. Calcium hypochlorite continued to be the bleaching agent used but multistage bleaching processes began to be employed. After World War I, compressed chlorine gas became available and its well-established properties as a delignifying agent ultimately resulted in its use in a chlorine-caustic extraction-hypochlorite (CEH) bleaching sequence. By the 1950s, chlorine dioxide generators were developed leading to the extensive use of this chemical as a bleaching agent particularly for the hard to bleach Kraft pulp. More recently peroxygens, particularly hydrogen peroxide, have been utilized. See also **Pulp (Wood) Production and Processing**.

Household and Commercial Laundering. Prior to the turn of the twentieth century home bleaching in the United States was accomplished by the same method used by the ancient Romans and Gauls. Clothes were laundered in a mildly alkaline bath and then subjected to sunlight bleaching. In the period from 1910 to 1920, 5.25% sodium hypochlorite solutions were developed and distributed regionally in the United States. By the mid-1930s these solutions were available nationwide. This formula has remained essentially unchanged since its initial introduction. In the 1950s laundry products containing dry sources of hypochlorite were introduced into the United States. However, by the late 1960s the dry chlorine products had disappeared probably because of lower efficacy compared to liquid hypochlorite and fabric damage resulting from placement of the product on wet fabric. In Europe, laundry detergents containing sodium perborate as a bleaching agent were introduced in the early 1900s. The perborate dissolves during the laundering process and releases hydrogen peroxide. Sodium perborate continues to be heavily used in European laundry detergents because of the high (up to 95 °C) wash temperatures. In the 1950s, laundry products containing sodium perborate were introduced in the United States. In the late 1970s, tetraacetylethylenediamine (TAED), a perborate activator, was introduced into European detergents. TAED with perborate generates peracetic acid in the wash, which is more effective than hydrogen peroxide. TAED is currently contained in >50% of European detergents. In the United States in 1982 a dry bleach containing diperoxydodecanedioic acid was test marketed but not expanded. In the late 1980s, a detergent product containing the perborate activator nonanoyloxybenzene sulfonate was introduced. This activator generates pernonanoic acid when combined with hydrogen peroxide generated from sodium perborate monohydrate.

Commercial laundries have used and continue to use sodium hypochlorite as the primary bleaching agent because of its whitening and disinfectant properties.

Chlorine-Containing Bleaching Agents

Chlorine-containing bleaching agents are the most cost-effective bleaching agents known. They are also effective disinfectants, and water disinfection is often the largest use of many chlorine-containing bleaching agents. They may be divided into four classes: chlorine, hypochlorites, *N*-chloro compounds, and chlorine dioxide.

The first three classes are called available chlorine compounds and are related to chlorine by the equilibria in equations 1–4. These equilibria are rapidly established in aqueous solution, but the dissolution of some hypochlorite salts and *N*-chloro compounds can be quite slow.

$$Cl_2(gas) \rightleftharpoons Cl_2(aq) \tag{1}$$

$$Cl_2(aq) + H_2O) \rightleftharpoons HOCl + H^+ + Cl^- \tag{2}$$

$$HOCl \rightleftharpoons H^+ + OCl^- \tag{3}$$

$$RR'NCl + H_2O \rightleftharpoons HOCl + RR'NH \tag{4}$$

The total concentration or amount of chlorine-based oxidants is often expressed as available chorine, or less frequently as active chlorine. Available chlorine is the equivalent concentration or amount of Cl_2 needed to make the oxidant according to equations 1–4. Active chlorine is the equivalent concentration or amount of Cl atoms that can accept two electrons. This is a convention, not a description of the reaction mechanism of the oxidant. Because Cl_2 only accepts two electrons as does HOCl and monochloramines, it only has one active Cl atom according to the definition. Thus the active chlorine is always one-half of the available chlorine. The available chlorine is usually measured by iodometric titration. The weight of available chlorine can also be calculated by equation 5, where 70.9 represents the mol wt of Cl_2 and moles of oxidant can be represented wt oxidant/mol wt of oxidant.

$$\text{weight available} = 70.9 \times \text{moles of oxidant} \times \frac{\text{number active Cl atoms}}{\text{molecule}} \tag{5}$$

In solutions, the concentration of available chlorine in the form of hypochlorite or hypochlorous acid is called free-available chlorine.

Commercially important solid available chlorine bleaches are usually more stable than concentrated hypochlorite solutions. They decompose very slowly in sealed containers. But most of them decompose quickly as they absorb moisture from air or from other ingredients in a formulation. This may release hypochlorite that destroys other ingredients as well.

Chlorine. Except to bleach wood pulp and flour, chlorine [CAS: 7782-50-5] itself is rarely used as a bleaching agent. Chlorine is almost always first converted into one of the bleaching agents described, and they are almost always used at a pH where Cl_2 is not present. However, it has been the practice to use acid chlorination where Cl_2 is the active species in the first step of pulp bleaching. Since chlorine reacts primarily by chlorination, large amounts of chlorinated organic by-products are formed. Environmental concerns about discharging these by-products in waste effluents are rapidly changing this process.

Hypochlorites. The principal form of hypochlorite produced is sodium hypochlorite [CAS: 7681-52-9], NaOCl. It is invariably made and used as an aqueous solution and is usually prepared by the chlorination of sodium hydroxide solutions, though other bases such as sodium carbonate can be used.

Other hypochlorites include calcium hypochlorite [CAS: 7778-54-3], bleach liquor, bleaching powder [CAS: 64175-94-6] and tropical bleach, dibasic magnesium hypochlorite, lithium hypochlorite [CAS: 13840-33-0], chlorinated trisodium phosphate [CAS: 11084-85-8], and hypochlorous acid [CAS: 7790-92-3].

Hyprobromites. The chemistry of hypobromite is similar to hypochlorite. It reacts faster than hypochlorite and gives better bleaching at higher pH and lower temperatures. It also decomposes much faster than hypochlorite. The most stable solutions decompose quickly and must be freshly prepared. This can be done by adding a bromide salt to a hypochlorite solution, since hypochlorite oxidizes bromide to hypobromite. Usually a catalytic amount of bromide is used since much of it will be regenerated as the hypobromite is reduced during bleaching. Dry compositions containing a bromide salt and a solid available chlorine compound can also be used. A few N-bromo compounds are also available.

N-Chloro Compounds. The principal solid chlorine bleaching agents are the chlorinated isocyanurates. The one used most often for bleaching applications is sodium dichloro-isocyanurate dihydrate [CAS: 51580-86-0], with 56% available chlorine. It is the most water-soluble, the fastest to dissolve, and the least hazardous. It has good stability and compatibility with other dry ingredients.

Chlorine dioxide [CAS: 10049-04-4], ClO_2, is a gas that is more hazardous than chlorine. It can explode at concentrations >10% in air. The liquid boils at 11 °C but explodes above −40 °C. It can be stored and transported as its octahydrate if kept frozen, but almost all chlorine dioxide is made on site for immediate use. Large amounts for pulp bleaching are made by several processes in which sodium chlorate [CAS: 7775-09-9] is reduced with chloride, methanol, or sulfur dioxide in highly acidic solutions by complex reactions. For most other purposes chlorine dioxide is made from sodium chlorite [CAS: 7758-19-2].

The biggest use of chlorine dioxide is in bleaching wood pulp. In some mills, much of the chlorine and hypochlorite has been replaced by chlorine dioxide to reduce the amount of chlorinated by-products. Chlorine dioxide is also used to bleach textiles, flour, and edible fats and oils.

Peroxygen Compounds

Peroxygen compounds contain the peroxide linkage (−O−O−) in which one of the oxygen atoms is active. This activity, referred to as active oxygen (AO), is measured by the oxidation of iodide to iodine under acidic conditions or by a ceric sulfate titration. Active oxygen content, usually expressed as a percent, is the atomic weight of active oxygen divided by the molecular weight of the compound

Hydrogen peroxide [CAS: 7722-84-1] is one of the most common bleaching agents. See also **Hydrogen Peroxide**. It is the primary bleaching agent in the textile industry, and is also used in pulp, paper, and home laundry applications. In textile bleaching, hydrogen peroxide is the most common bleaching agent for protein fibers, and is also used extensively for cellulosic fibers.

Hydrogen peroxide reacts with many compounds, such as borates, carbonates, pyrophosphates, sulfates, silicates, and a variety of organic carboxylic acids, esters, and anhydrides to give peroxy compounds or peroxyhydrates. A number of these compounds are stable solids that hydrolyze readily to give hydrogen peroxide in solution.

Sodium perborate [CAS: 7632-04-4] is the most widely used solid peroxygen compound. Commercially, it is available as a tetrahydrate [CAS: 10486-00-7] and a monohydrate [CAS: 10322-33-9]. The tetrahydrate is produced by treating a borax solution with hydrogen peroxide and sodium hydroxide. Other agents in the category are Sodium carbonate peroxyhydrate [CAS: 15630-89-4], Peroxymonosulfuric acid (Caro's acid) [CAS: 7722-86-3].

Peracids. Peracids are compounds containing the functional group O−OH derived from an organic or inorganic acid functionality. Typical structures include $CH_3C(O)OOH$ derived from acetic acid and $HOS(O)_2OOH$ (peroxymonosulfuric acid) derived from sulfuric acid. Peracids have superior cold water bleaching capability versus hydrogen peroxide because of the greater electrophilicity of the peracid peroxygen moiety. Lower wash temperatures and phosphate reductions or bans in detergent systems account for the recent utilization and vast literature of peracids in textile bleaching.

Peracids can be introduced into the bleaching system by two methods. They can be manufactured separately and delivered to the bleaching bath with the other performance components or as a separate product. Peracids can also be formed *in situ* utilizing the perhydrolysis reaction shown in equation 6.

$$\mathrm{R{-}\overset{\overset{O}{\|}}{C}{-}Z + {}^{-}OOH \longrightarrow \overset{\overset{O}{\|}}{R}COOH + Z^{-}} \qquad (6)$$

Peracid Precursor Systems. Compounds that can form peracids by perhydrolysis are almost exclusively amide, imides, esters, or anhydrides. Tetraacetylethylenediamine [CAS: 10543-57-4] (TAED) is utilized in over 50% of Western European detergents. Nonanoyloxybenzene sulfonate [CAS: 101482-85-3] (NOBS) is used in detergent products in the United States and Japan.

Preformed Peracids. Peracids can be generated at a manufacturing site and directly incorporated into formulations without the need for *in situ* generation. Two primary methods are utilized for peracid manufacture. The first method uses the equilibrium shown in equation 7 to generate the peracid from the parent acid.

$$\mathrm{\overset{\overset{O}{\|}}{R}COH + H_2O_2 \rightleftharpoons \overset{\overset{O}{\|}}{R}COOH + H_2O} \qquad (7)$$

The equilibrium is shifted by removal of the water or removal of the peracid by precipitation. Peracids can also be generated by treatment of an anhydride with hydrogen peroxide to generate the peracid and a carboxylic acid.

$$\mathrm{\overset{\overset{O}{\|}}{R}C\overset{\overset{O}{\|}}{O}CR + H_2O_2 \longrightarrow \overset{\overset{O}{\|}}{R}COOH + \overset{\overset{O}{\|}}{R}COH} \qquad (8)$$

The latter method (eq. 8) typically requires less severe conditions than the former because of the labile nature of the organic anhydride. Both of these reactions can result in explosions, and significant precautions should be taken prior to any attempted synthesis of a peracid.

Reducing Bleaches

The reducing agents generally used in bleaching include sulfur dioxide, sulfurous acid, bisulfites, sulfites, hydrosulfite (dithionites), sodium sulfoxylate formaldehyde, and sodium borohydride. These materials are used mainly in pulp and textile bleaching. See also **Boron**; and **Sulfur**.

The Mechanism of Bleaching

Bleaching is a decolorization or whitening process that can occur in solution or on a surface. The color-producing materials in solution or on fibers are typically organic compounds that possess extended conjugated chains of alternating single and double bonds and often include heteroatoms, carbonyl, and phenyl rings in the conjugated system. The portion of molecule that absorbs a photon of light is referred to as the chromophore (Greek: *color bearer*). For a molecule to produce color the conjugated system must result in sufficiently delocalized electrons such that the energy gap between the ground and excited states is small enough so that photons in the visible portion of the light spectrum are absorbed.

Bleaching and decolorization can occur by destroying one or more of the double bonds in the conjugated chain, by cleaving the conjugated chain, or by oxidation of one of the other moieties in the conjugated chain. The result of any one of the three reactions is an increase in the energy gap between the ground and excited states, so that the molecule then absorbs light in the ultraviolet region, and no color is produced. Bleaching may also increase the water solubility of organic compounds after reaction. Conversion of an olefin to a vicinal diol, for example, dramatically increases the polarity and consequently the water solubility of the compound. A variety of bleaching agents can affect this transformation. The increased solubility allows actual removal of the bleached substance from a surface.

Chlorine bleaches react with more chromophores than oxygen bleaches. They react irreversibly with aldehydes, alcohols, ketones, carbon−carbon double bonds, acidic carbon−hydrogen bonds, nitrogen compounds, sulfur compounds, and aromatic compounds.

The mechanism of bleaching of hydrogen peroxide is not well understood. It is generally believed that the perhydroxyl anion (HOO^-) is the active bleaching species since both the concentration of this anion and the rate of the bleaching process increase with increasing pH. Hydrogen peroxide and other peroxygen compounds can destroy double bonds by epoxidation. This involves addition of an oxygen atom across the double bond usually followed by hydrolysis of the epoxide formed to 1,2-diols under bleaching conditions.

Peracids undergo a variety of reactions which result in bleaching. Peracids can add an oxygen across a double bond to give an epoxide, which can undergo further reactions including hydrolysis to give a vicinal diol. Peracids can oxidize aldehydes to acids, sulfur compounds to sulfoxides and sulfones, and nitrogen compounds to amine oxides, hydroxylamines, and nitro compounds. Peracids can also oxidize α-diketone compounds to anhydrides and ketones to esters.

Reducing agents are thought to work by reduction of the chromophoric carbonyl groups in textiles or pulp.

Applications of Bleaching Compounds

Laundering and Cleaning. The most widely used bleach in the United States is liquid chlorine bleach, an alkaline aqueous solution of sodium hypochlorite. This bleach is highly effective at whitening fabrics and also provides germicidal activity at usage concentrations. Liquid chlorine bleach is sold as a 5.25% solution, and 1 cup provides 200 ppm of available chlorine in the wash. Liquid chlorine bleaches are not suitable for use on all fabrics. Dry and liquid bleaches that deliver hydrogen peroxide to the wash are used to enhance cleaning on fabrics. They are less efficacious than chlorine bleaches but are safe to use on more fabrics. The dry bleaches typically contain sodium perborate in an alkaline base whereas the liquid peroxide bleaches contain hydrogen peroxide in an acidic solution. Detergents containing sodium perborate tetrahydrate are also available. See also **Detergents**; and **Oxidation and Oxidizing Agents**.

The worldwide decreasing wash temperatures, which decrease the effectiveness of hydrogen peroxide-based bleaches, have stimulated research to identify activators to improve bleaching effectiveness. Tetraacetylethylenediamine is widely used in European detergents to compensate for the trend to use lower wash temperatures. TAED generates peracetic acid in the wash in combination with hydrogen peroxide. TAED has not been utilized in the United States, where one activator nonanoyloxybenzene sulfonate (NOBS) has been commercialized and incorporated into several detergent products. NOBS produces pernonanoic acid when combined with hydrogen peroxide in the washwater and is claimed to provide superior cleaning in contrast to perborate bleaches.

In industrial and institutional bleaching, either liquid or dry chlorine bleaches are used because of their effectiveness, low cost, and germicidal properties. Dry chlorine bleaches, particularly formulated chloroisocyanurates, are used in institutional laundries.

Bleaching agents are used in hard surface cleaners to remove stains caused by mildew, foods, etc, and to disinfect surfaces. Disinfection is especially important for many industrial uses. Alkaline solutions of 1–5% sodium hypochlorite that may contain surfactants and other auxiliaries are most often used for these purposes. These are sometimes thickened to increase contact times with vertical surfaces. A thick, alkaline cleaner with 5% hydrogen peroxide is also sold in Europe. Liquid abrasive cleansers with suspended solid abrasives are also available and contain about 1% sodium hypochlorite. Powdered cleansers often contain 0.1–1% available chlorine and they may contain abrasives. Sodium dichloroisocyanurate is the most common bleach used in powdered cleansers, having largely replaced chlorinated trisodium phosphate. Calcium hypochlorite is also used. Dichloroisocyanurates are also used in effervescent tablets that dissolve quickly to make cleaning solutions. In-tank toilet cleaners use calcium hypochlorite, dichloroisocyanurates, or *N*-chloro compounds to release hypochlorite with each flush.

The primary role of bleach in automatic dishwashing and warewashing is to reduce spotting and filming by breaking down and removing the last traces of adsorbed soils. They also remove various food stains such as tea. All automatic dishwashing and warewashing detergents contain alkaline metal salts or hydroxides.

Textile Bleaching. Many textiles are bleached to remove any remaining soil and colored compounds before dyeing and finishing (see **Textiles**). Bleaching is usually preceded by washing in hot alkali to remove most of the impurities in a process called scouring. Bleaching is usually done as part of a continuous process, but batch processes are still used. Bleaching conditions vary widely, depending on the equipment, the bleaching agent, the type of fiber, and the amount of whiteness required for the end use.

Cotton is the principal fiber bleached today, and almost all cotton is bleached. About 80–90% of all cotton and cotton–polyester fabric is bleached with hydrogen peroxide.

Rayon is bleached similarly to cotton but under milder conditions since the fibers are more easily damaged and since there is less colored material to bleach.

Most synthetic fibers are sufficiently white and do not require bleaching. When needed, synthetic fibers and many of their blends are bleached with sodium chlorite solutions. Solutions of 0.1% peracetic acid are also used.

Wool must be bleached carefully, in order to avoid fiber damage. It is usually bleached with 1–5% hydrogen peroxide solutions. Silk is bleached similarly, but at slightly higher temperatures.

Bleaching of Other Materials. Hydrogen peroxide is the most satisfactory bleaching agent for human hair.

The coloring matter in fur is usually bleached using hydrogen peroxide stabilized with sodium silicate.

Sulfur dioxide is used to preserve grapes, wine, and apples; the process also results in a lighter color. During the refining of sugar, sulfur dioxide is added to remove the last traces of color. Flour can be bleached with a variety of chemicals including chlorine, chlorine dioxide, oxides of nitrogen, and benzoyl peroxide. Bleaching agents such as chlorine dioxide or sodium dichromate are used in the processing of nonedible fats and fatty oils for the oxidation of pigments to colorless forms. BLEAK *(Osteichthyes).* Small fishes (*Alburnus*) of several species found in Europe and western Asia, related to the carps. Scales are used for the manufacture of artificial pearls.

BLEEDER RESISTANCE. A resistor permanently connected across the output of a power supply. The primary function of this resistor is to discharge the filter capacitors used in the supply when power is disconnected.

BLENDING. See **Mixing and Blending**.

BLENDING HEIGHT. A height scale for turbulent flow above an inhomogeneous surface, at which the influences of individual surface patches on vertical profiles or fluxes become horizontally blended.

Below this height scale it is not permissible to treat the structure of turbulence as horizontally uniform. Some authors distinguish between 1) the physical blending height, where local perturbations become negligible due to turbulent mixing, and 2) the numerical blending height in numerical models, above which the horizontal average of locally variable profiles (e.g., wind speed) corresponds to a similarity profile. Both of these height scales are related to the length scale of horizontal surface variations and, typically, the physical blending height is an order of magnitude higher than the numerical blending height.

AMS

BLENNIES *(Osteichthyes).* Of the suborder *Blennioidei*, blennies are generally elongated, often eel-like fishes. They have been found in marine deposits as far back as the Eocene era (about 50 million years ago). Present-day blennies primarily inhabit the floors of tropical, temperate, and arctic seas, and in just a few cases, they are found in fresh water. The smallest species attain a length of an inch or less (few centimeters), while the largest blenny is the *wolffish* (*Anarrhichas minor*), which attains a length up to 6 feet (1.8 meters). In most families, the scales are either

greatly degenerate or are completely absent. In the latter case, the skin is equipped with many slime-secreting glands. The slime has the same protective function as scales.

The dorsal and anal fins of blennies are well developed; the dorsal fin extends from the rear of the body, and the anal fin extends from about the middle of the body to the caudal fin. In some species, the anal and caudal fins have fused together, forming a uniform fin seam. The pelvic fins are either degenerate or absent. The pelvic girdle, when present, is also poorly developed, and has fused with the lower part of the pectoral girdle. Of the total of 15 families, the blennies, tripterygiids, clipfishes, chaenopsids, and another family (*Congrogadidae*) are distributed in tropical and temperate waters. Four small blenny families are found in the Australian region. The wolffishes (see Fig. 1), the pricklebacks, and the gunnels chiefly inhabit arctic areas. Three other families, the quillfishes (*Ptilichthyidae*), the graveldivers (*Scytalinidae*), and the prowfishes (*Zaproridae*) are only found in the north Pacific Ocean.

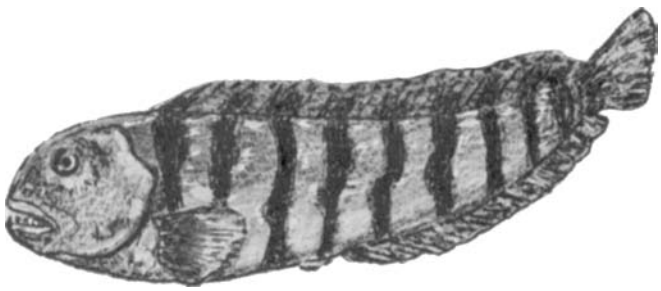

Fig. 1. Wolffish (*Anarrhichas lupus*).

The blennies (*Blenniidae*) form the largest and most diverse family in the suborder. These species are found in deep water, at the water surface, and even on land. A few species have invaded fresh water habitats. Blennies are found above hard, rocky bottom, or sometimes soft mangrove mud. While most blennies are bottom dwellers, some species have taken up a free-swimming existence. One of the most prominent blenny characteristics is the presence of simple or treelike branching tentacles on the heads of many species. They may be located in front of the lowest nasal openings, above the eyes, and/or on the rear of the head. In other species, a helmet-shaped lobe of skin, the comb, is present. Tentacles and the comb can differ in size between males and females, and they may degenerate outside the spawning season. Females often lack a comb entirely.

Over the centuries, two blenny subfamilies have developed, and their differing diet forms the basis of this division. *Blenniidae* blennies feed chiefly on chaetognaths (bristle worms), crustaceans, and mollusks, eating some plant matter. Thus, their dentition and intestinal tract are well developed. These species have immovable teeth in their jaws, including larger chewing teeth at the ends. *Runula* and other genera have well-developed canine teeth in both upper and lower jaws. A few of these species have taken up a striking means of feeding; they attack larger fishes and tear pieces of their skin and fins out with their powerful teeth. The stomach-less intestinal tract in *Runula* and related genera is short. The *Salariinae* blennies have fine, movable teeth with which they scrape algae from rocks. In order that their pure plant diet can be best utilized, their intestinal tract is relatively long, and leads to the anus with several convolutions.

As bottom dwellers, blennies usually lack a swim bladder. At one time, the life habits of *Blenniidae* blennies were known only through aquarium observations. In more recent times, divers have studied their actions in their natural habitats. Vision is their most important sensory modality, and it plays the most important sensory role; smell is less important; and their sense of vibration is not well developed. *Blenniidae* blennies can rapidly change their coloration pattern, frequently used for camouflaging. See also **Fishes**.

BLEPHARITIS. Blepharitis is an inflammation of the eyelids that can affect persons of all ages. Excess oil is produced in the glands near the eyelid, which creates a favorable environment for the growth of bacteria. It is a common condition that has multiple causes. The three most prevalent forms of this condition are seborrheic, staphyloccocal, and mixed. Another less common, but severe form of blepharitis, is ulcerative blepharitis.

Seborrheic blepharitis, the least severe and most common form, is often associated with dandruff of the scalp or acnelike skin conditions. It is a dysfunction of a type of gland that exists in the eyelid and the skin. This type of blepharitis usually affects the mature population and appears as greasy flakes or scales around the base of the eyelashes and as a mild redness of the eyelid. Symptoms are itchiness, foreign body sensation, discharge, and burning.

Staphylococcal blepharitis is an infection of the eyelids and commonly begins in childhood, continuing throughout adulthood. Invading bacteria cause inflammation of the eyelids and produce irritants and bacteria toxins that are harmful to the eye. Crusting, scaling, hair losses, chronic redness, and whitening of lashes are common symptoms. Treatment is most important to prevent potential scarring of the cornea and conjunctiva.

Mixed blepharitis is a combination of both seborrhea and staphyloccocal forms of this condition, and symptoms of both types can appear.

Ulcerative blepharitis is characterized by matted hard crusts around the eyelashes, that result in small sores that may bleed or ooze when removed. Loss of eyelashes, distortion of the front edges of the eyelids, and chronic tearing may also occur. The cornea may also become inflamed.

In any form of blepharitis, the conjunctiva and cornea can be affected. Even mild conditions can be uncomfortable and unattractive, and if untreated, can lead to more serious problems. Complications such as prolonged infection, injury to the eye tissue from irritation (corneal ulcer), inflammation of the conjunctiva, loss of eyelashes, and scarring of the eyelids may occur.

Good eyelid hygiene is essential in treating blepharitis. Warm, moist compresses can also help relieve symptoms when used in conjunction with regular eyelid cleansing. Because staphylococcal blepharitis is an infection, antibiotics and/or corticosteroids can treat the infection and help reduce the swelling.

Although chronic and bothersome, blepharitis can be controlled. Symptoms, however, are chronic, recurring, and remitting, and there may be no definitive cure. The problem can disappear for long periods of time and then return. Medication alone is not sufficient treatment, and keeping the eyelids clean is essential to restoring a normal, healthy environment.

Vision Rx, Inc., Elmsford, NY

BLEPHAROPLASTY. Blepharoplasty is cosmetic surgery that removes wrinkled, droopy skin from the upper eyelids and bags below the eyes.

Although some appearance problems may be hereditary, most are due to age. As a person grows older, the skin can lose elasticity, resulting in a creased, droopy appearance. Psychological outlook can also influence appearance, as grief or worry accelerates the aging process.

The operation is done by making incisions in the fold of the lid and just below the lower line of the lash. Excess tissue is removed, and the incisions are stitched carefully so that any scar runs in a natural crease line. Ice packs and pads soaked with witch hazel solution are applied to reduce swelling and bruising, both at the medical center immediately after the surgery and during recuperation at home. The swelling usually goes down after three days, but bruises may be visible for up to two weeks. Some stitches are taken out 3 to 5 days after the operation, and the others are removed in 7 or 10 days.

Most complications of blepharoplasty are not long lasting. There may be hematomas, swellings filled with blood, but they do not cause lasting damage. A patient may experience double vision for a few hours after the operation, and some people have excess tearing for a few days. Some patients may not be able to close their eyes completely for several days. If the problem persists, eye drops may be prescribed to reduce irritation. If cysts form along the incision, they can be removed easily. The most

serious complication is ectropion, a turning out of the eyelid if too much tissue is removed. It can be corrected by skin grafts.

Vision Rx, Inc., Elmsford, NY

BLEPHAROSPASM. A blepharospasm is a chronic continuous involuntary blinking or forcible closure of the eyelids. It is caused by dysfunction of the area of the brain that controls the muscles around the eye. Other facial muscles can twitch as well, particularly those around the cheek and brow. Severe cases can cause the eyelids to forcibly close for a longer period than the typical blink, disrupting vision.

Symptoms occur most frequently in persons who are between the ages of 50 and 70. Women are three times more likely to develop the condition than men are.

Blepharospasm should not be confused with ptosis, which is drooping of the eyelids caused by weakness or paralysis of a muscle in the upper eyelid. Another condition, called hemifacial spasm, affects muscles on one side of the face, often including the eyelid. The muscle contractions from this disorder are more rapid and transient, and they always affect just one side of the face. Blepharospasm usually affects both eyes.

Mild cases of blepharospasm are sometimes treated with medications. However, drug therapy is difficult, because there is no fixed or best regime. One drug may work for some patients and not for others. Biofeedback training can also be helpful in mild cases. Walking, extra sleep, talking, and relaxation techniques may lessen symptoms. Unfortunately, most cases require treatment beyond these measures.

The preferred treatment for many patients is the injection of botulinum toxin (Botox). Although the same bacterium responsible for botulism food poisoning produces this toxin, it is safe in minute doses and effective in stopping eyelid spasms. Botulinum toxin is injected with a very fine needle into the eyelid, the brow, or the muscles under the lower lid. It starts working in 1 to 14 days and lasts an average of 3 to 4 months. Then the patient needs another injection.

Long-term studies have shown that Botox injections are safe and effective for 90 percent of patients. Side effects can be drooping eyelids, blurred vision, double vision, and excessive tearing. These are usually minor and correct themselves.

Patients who have not responded well to medication or botulinum toxin may be candidates for surgical therapy. Removing some or all of the muscles responsible for eyelid closure is the most effective surgical treatment for blepharospasm.

Vision Rx, Inc., Elmsford, NY

BLIND-FISH *(Osteichthyes).* Also sometimes referred to as cave dwellers, these fishes are members of the suborder *Characoidei*, and of the family *Amblyopsidae*, of which there are three genera, including the southern cavefish (*Typhlichthys subterraneus*), the ricefish (*Chologaster cornuta*), the springfish (*Chologaster agassizi*), the northern cavefish (*Amblyopsis spelaea*), and the Ozark cavefish (*Amblyopsis rosae*). These all are whitish-appearing fishes that generally reach a maximum size of about $3\frac{1}{2}$ inches (9 centimeters). With exception of one species, these fishes are found in the limestone region of the central United States, essentially between the Appalachian Mountains and the Great Plains, south of the limit of glaciation and north of the Cretaceous Mississippi embayment. However, the ricefish displays no correlation with limestone areas. It is found on the Atlantic coastal plain. Unlike the other species, the ricefish does not occur in caves, but is found in streams and cypress swamps. This species has very small functional eyes, but laboratory experiments have shown that it can obtain its food just as well without the eyes. The other amblyopsids, of course, are blind, but do display a rudimentary eye. Generally, the amblyopsids lack pigment, but it has been found experimentally that, if the southern cavefish is retained in a day-lighted aquarium for a period of three months or longer, pigment coloration can be developed.

Until relatively recently, cave fishes were considered the only examples of blind characins, although there are several blind carp and catfish species. In 1965, while laborers were digging a well in Brazil, another blind characin (*Stygichthys typhlops*) was discovered. It was found at a level about 100 feet (30 meters) below ground level. This fish not only lacks eyes and normal pigmentation, but also the lateral line organ, considered so important for blind forms. The bones that normally cover the eye region have disappeared, along with most pores on the head and important sensory organs. Another special case is found in the southernmost characin of all — *Gymnocharacinus*. It is completely naked, without the slightest trace of scales. For a while, this was also believed to be an exceptional case, but later a completely naked characin was discovered in Ghana.

In terms of blind fishes in general, it is now believed that the regression of the eyes and pigments is not a direct result of the darkness in which the species spends its entire life. If it is kept under daylight conditions in an aquarium and bred under these conditions for many generations; the vision still remains poor and the eyes are degenerate. One must conclude that the degeneration of the eyes and pigments is an inherited trait. In spite of this great discrepancy between the river fishes with normal vision and the blind cave fishes, they can be crossed (considered not only unusual, but quite unexpected). Thus, the courtship behavior in both forms must correspond to a high degree. The hybrid from such a cross is a mixture between the river inhabitant and the cave fish. It has small eyes, is clearly colored and completely fertile; it can be crossed with one of the parents or with another hybrid. In the latter case, a second generation is produced which varies from species with full vision to those that are completely blind. Coloration varies tremendously also in this third generation. Interestingly, there are pigment-less forms with well-developed vision and blind but fully colored fishes. Geneticists have concluded the following:

1. Development of pigmentation and the eyes proceed independently and are inherited independently.

2. The differences between river fishes and cave fishes arise from mutations. In the transition to cave life, those characteristics that have become useless degenerate by changes in the gene structure. This process in the fishes is a model for the general degeneration of organs throughout the animal kingdom, if not solely for the degeneration of pigmentation and eyes in other cave-dwelling animals.

It can be estimated how long it took for the colorless blind fishes to develop from the normal fishes. *Astyanax fasciatus mexicanus*, which lives above ground, is originally from South America. It could have penetrated Mexico toward the end of the Tertiary period (about 1 million years ago) when the land bridge between South and North America was formed. It could not have invaded Mexico any earlier because it is a fresh-water fish. However, the caves into which it moved were formed during the Ice Age rainy period $\frac{1}{2}$ million years ago through an outgrowth of the calciferous stone deposits. Thus, it could have taken at most $\frac{1}{2}$ million years for the blind varieties to develop from normal fishes. The earlier cave rivers dried up during the drought of the Ice Age, so that these present-day cave fishes inhabit just a few scattered grottos.

BLIND WORM *(Amphibia, Gymnophiona).* Slender, burrowing worm-like amphibians with no trace of legs and with the tail and eyes rudimentary. They are also called caecilians.

BLISTER BEETLE *(Insecta, Coleoptera).* Soft-bodied beetles of medium to large size. They are named from their blistering properties; when crushed on the skin even the common species are capable of raising a blister.

Blister beetles are a source of a preparation known as Spanish fly, from the species of that name. This material is composed of the dried pulverized bodies of the insects and is used for producing blisters. Some of the North American species are also occasionally important enemies of plants, among them the old-fashioned potato beetle. They can be checked by the application of sprays containing arsenical poisons.

Several hundred species of blister beetles have been described. They constitute the family *Meloidae*.

BLIZZARD. A blizzard is a severe weather condition characterized by high winds and reduced visibilities due to falling or blowing snow. The U.S. National Weather Service specifies a wind of 30 knots (35 miles per hour) or greater, sufficient snow in the air to reduce visibility to less than

400 meters (0.25 miles). Earlier definitions also included a condition of low temperatures, on the order of −7 °C (20 °F) or lower, or −12 °C (10 °F) or lower (severe blizzard). The name originated in the United States but it is also used in other countries. In the Antarctic the name is given to violent autumnal winds off the ice cap. In southeastern France, the cold north wind with snow is termed blizzard or *boulbie*. Similar storms in Russian Asia are the *buran* and *purga*. In popular usage in the United States and in England, the term is often used for any heavy snowstorm accompanied by strong winds.

An extreme form of blizzard is a *whiteout*, when downdrafts coupled with snowfall become so severe that it is impossible to distinguish the ground from the air. People caught in a whiteout can quickly become disoriented, losing their sense of direction. This poses difficulty for aviation flying in the altitude of the storm.

Certain types of blizzards in the northeastern United States are colloquially known as *Nor'easters*. In the Upper Midwest, a northerly weather pattern deemed likely to produce blizzards is called an Alberta clipper. See also **Nor'easter**.

Boulbie

In France, a violent north wind in the Ariège valley south of Toulouse, especially in December and January. It is strong enough to uproot chestnut trees; it is cold and dry, but may pick up snow from the ground and form drifts.

Buran

A strong northeast wind in Russia and central Asia. It is most frequent in winter when it resembles a blizzard, that is, very cold and lifting snow from the ground; as such it is called white buran or, on the tundra, purga. A similar wind in Alaska is called *burga*. The buran also occurs, but less frequently, in summer, when it raises dust clouds; it is then called *karaburan*.

Burga

(Also spelled boorga.) A northeasterly storm in Alaska, bringing sleet or snow; it is similar to the winter buran or purga of Russia and Siberia.

Purga

(Also spelled poorga.) In Russia, a severe storm, similar to the blizzard and buran, that rages in the tundra regions of northern Siberia in winter.

BLOB. A radar term referring to a fairly small-scale temperature and moisture nonhomogeneity produced by turbulence within the atmosphere. The resulting abnormal gradient of the refractive index can produce a radar echo of the type known as angels.

BLOCH FUNCTION. It can be shown that the wave function of an electron in a periodic lattice has the form

$$\psi = u(\mathbf{r})e^{i\mathrm{k}_\mathrm{I}r}$$

where $u(\mathbf{r})$ has the periodicity of the lattice (i.e., is the same in every unit cell) and k is the wave vector of the electron. Notice that this corresponds to a plane wave modulated by the periodicity of the lattice.

BLOCH WALL. This is a transition layer between adjacent ferromagnetic domains magnetized in different directions. The wall has a finite thickness, of the order of a few hundred lattice constants, as it is energetically preferable for the spin directions to change slowly from one orientation to another, going through the wall, rather than to have an abrupt discontinuity. The concept of Bloch wall is useful in solid state physics, especially in ferromagnetic theory.

BLOCKING. 1. The obstructing, on a large scale, of the normal west-to-east progress of migratory cyclones and anticyclones. A blocking situation is attended by pronounced meridional flow in the upper levels, often comprising one or more closed anticyclonic circulations at high latitudes and cyclonic circulations at low latitudes (cut-off highs and cut-off lows). This anomalous circulation pattern (the "block") typically remains nearly stationary or moves slowly westward, and persists for a week or more. Prolonged blocking in the Northern Hemisphere occurs most frequently in the spring over the eastern North Atlantic and eastern North Pacific regions.

2. The retardation of stable, low-level, forced upslope flow on the windward side of a mountain or mountain barrier; Smith (1979) asserts that "this windward-side slowing is due to the difficulty that the heavy [cold] surface air has in running upslope." The stable flow is characterized by having a Froude number much less than 1. In cases where a gapless mountain range is long enough to be a complete barrier to the flow, very stable air may be totally blocked or "dammed" (*see* damming), and the near-surface flow may be diverted back down the slope. If the blocking condition persists for more than a significant portion of a day, a barrier jet can form parallel to the mountain range. "In . . . flow near an isolated mountain or a ridge with ends or gaps, absolute blocking of flow is not possible. The layer of dense air may pile up slightly ahead of the mountain, but this can be relieved by airflow around the mountain or through gaps in the ridge" (*see also* gap wind). In stable flow (Froude number less than 1) over an isolated peak, the flow in the lower portions is partially blocked and diverts around the peak, whereas in the upper portion the flow can pass upward over the peak. The boundary between the lower and upper regions has been called the dividing streamline.

BLOCKING CAPACITOR. This is a capacitor used at various points in an electrical circuit where it is desirable to pass alternating currents and block direct currents. It is commonly used in coupling one transistor amplifier stage to the next succeeding one. Its use prevents the dc voltage at the output of one amplifier stage from affecting the operating point of the succeeding stage. See Fig. 1.

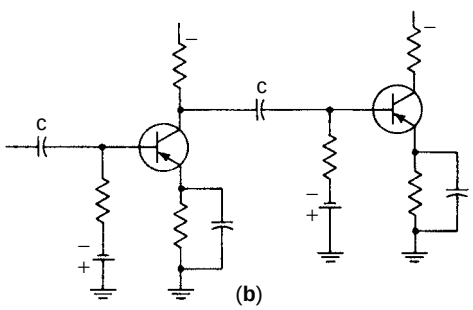

Fig. 1. Use of blocking capacitor (C) in electronic amplifier.

BLOOD. Classified as a major tissue of the human body, blood is a characteristically red, mobile fluid with an average specific gravity of about 1.058. Slightly sticky and somewhat viscous, blood has a viscosity between 4.5 and 5.5 times greater than that of water at the same temperature. Thus, blood flows somewhat more sluggishly than water. The odor of blood is characteristic; the taste is slightly saline. The pH of blood ranges between 7.35 and 7.45. The complex acid-base regulatory system of the blood is described in entry on **Acid-Base Regulation (Blood)**. Under normal conditions, the blood circulates through the body at a temperature of 100.4 °F (38.0 °C). This is slightly higher than the body temperature as determined by mouth, 98.6 °F (37.0 °C). An adult human of average age and size has just over 6 quarts (5.7 liters) of blood.

In very general terms, blood serves as a chemical transport and communications system for the body (i.e., it carries chemical messengers as well as nutrients, wastes, etc.). Circulated by the heart through arteries, veins, and capillaries, blood carries oxygen and a variety of chemicals to all cells, acting as a delivery agent to serve the needs of the cells. Blood also takes away waste products, including carbon dioxide, from the various tissues to organs such as the kidneys and lungs which ultimately dispose these wastes to the environment. Thus, the blood serves as a collecting agent. See also **Heart and Circulatory System (Physiology)**.

Unlike a simple liquid, such as water, or a simple solution, such as salt water, blood is a complex fluid made up of several components, each of which is, in turn, extremely complex and even today not fully

understood. Many of these substances are solids in suspension. Unlike most simple liquids that are not easily changed when exposed to air or to slight alterations in their environment, the physical and biochemical properties of blood undergo marked changes (Hemostatic responses) when blood is taken from the body's circulatory system and, for example, placed in a test tube. Separation of blood from its usual environment immediately initiates biochemical processes that alter its properties and cause it to release its components. When so removed, blood shortly becomes viscid and forms a soft, jelly-like substance, then soon separates into a firm solid mass (clot) and liquid (serum). This extremely important property of clotting is unique to blood among known inorganic and organic fluids and solutions. Were it not for this property, a person would bleed (hemorrhage) to death if a blood vessel were opened by accident or as the consequence of disease. Thus, blood may be described as a living fluid and most accurately as a living tissue, like the other tissues of the body.

Illustrative of the complex constitution of blood is the list of Table 1.

Principal Components of Human Blood

Not considering the numerous substances, other than oxygen, carried by the blood where the main function of the blood is one of transport, the main functional components of the blood are indicated in Fig. 1.

Erythrocytes. It is estimated that an adult man will have about 5 million erythrocytes per cubic millimeter of blood. This is equivalent to about 82 billion erythrocytes per cubic inch of blood. In an adult woman, there are about 4.5 million erythrocytes per cubic millimeter. Erythrocytes are homogeneous circular disks with no nucleus. These red cells are about 0.0077 millimeter in diameter. When viewed singly by transmitted light, the erythrocyte has a yellowish red tinge, but when viewed in great numbers, the erythrocytes have the distinctly blood red coloration. Erythrocytes possess a certain degree of elasticity, so that they can pass through tiny apertures and passages on their way to reach tissue supplied by the capillaries.

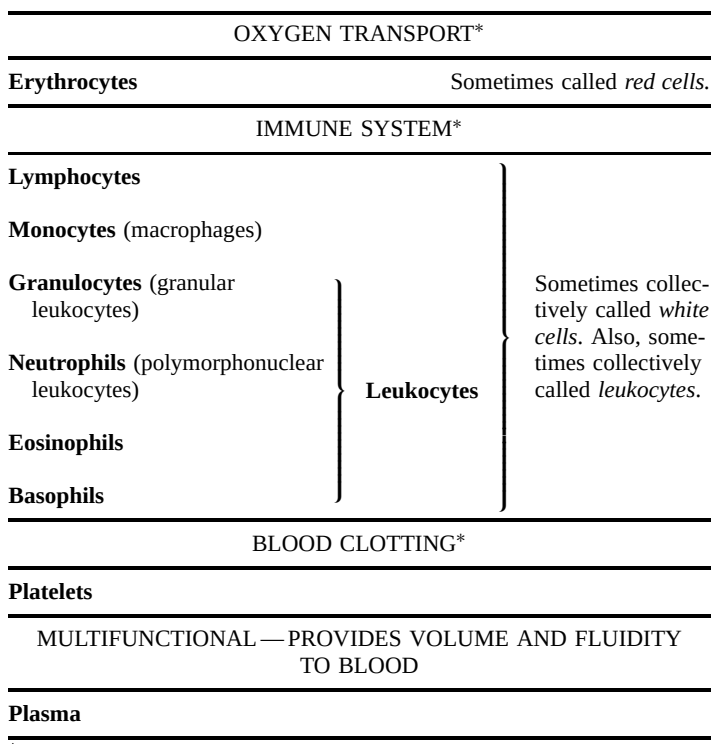
The prime function of the erythrocytes is to deliver oxygen to peripheral tissues. This oxygen is furnished to these cells by an exchange-diffusion system brought about in the lungs. The color of the erythrocytes is derived from a red iron-containing pigment called hemoglobin. This is a conjugated protein that consists of a globin (a protein) and hematin (a non-protein pigment), the latter containing iron. Hemoglobin contains 0.33% iron. When hemoglobin combines with oxygen, oxyhemoglobin is formed. When oxygen is given up to the tissues, it is then reduced back to hemoglobin. The erythrocytes also carry some carbon dioxide from the tissues and function to maintain a normal acid-base balance (pH) of the blood. When the hemoglobin has its full complement of oxygen, it is a bright red. This scarlet blood is found in the arteries that carry the blood to organ tissues throughout the body. As the oxyhemoglobin gives up oxygen, it takes on a darker crimson hue, and this is found in the veins which return the blood to the lungs for re-oxygenation. See **Hemoglobin**.

Megaloblasts. Cells that are the precursors of erythrocytes, are noted in the blood islands of the yolk sac of the human embryo. By the end

TABLE 1. REPRESENTATIVE CONSTITUENTS OF HUMAN BLOOD (VALUES ARE PER 100 MILLILITERS)

Constituent	Plasma of Serum	Whole Blood
Adenosine	1.09 mg	
Adenosine triphosphate (total)		31–57 mg
Amino acids (total)		38–53 mg
Ammonia N	0.1–1.1 mg	0.1–0.2 mg
Ascorbic acid	0.7–1.5 mg	0.1–1.3 mg
Base (total)	145–160 meq/liter	
Bicarbonate	25–30 meq/liter	19–23 meq/liter
Bile acids		0.2–3.0 mg
Biotin		0.7–1.7 μg
Blood volume		2990–6980 ml
— adult men	33.7–43.7 ml/kg	66.2–97.7 ml/kg
— adult women	32.0–42.0 ml/kg	46.3–85.5 ml/kg
— infants	36.3–46.3 ml/kg	79.7–89.7 ml/kg
Carbon dioxide		
— Arterial blood (total)		45–55 vol%
— Venous blood (total)		50–60 vol%
Cholesterol (total)	120–250 mg	115–225 mg
Cholesterol esters	75–150 mg	48–115 mg
Cholesterol (free)	30–60 mg	82–113 mg
Choline (total)	26–35 mg	11–31 mg
Fat (neutral)	25–260 mg	85–235 mg
Fatty acids	190–450 mg	250–390 mg
Fibrinogen	200–400 mg	120–160 mg
Fructose	7–8 mg	0–5 mg
Glucose (adult)	65–105 mg	80–120 mg
Hemoglobin	trace	14.8–15.8 g
Histamine		6.7–8.6 μg
Ketone bodies (total)	0.15–1.36 mg	0.23–1.00 mg
Lactic acid	30–40 mg	5–40 mg
Lecithin	100–225 mg	110–120 mg
Lipids (total)	400–700 mg	445–610 mg
Mucopolysaccharides	175–225 mg	
Mucoproteins	86.5–96 mg	
Nicotinic acid	0.02–015 mg	0.5–0.8 mg
Nitrogen (total)		3.0–3.7 g
Non-protein nitrogen	18–30 mg	25–50 mg
Nucleotide (total)		31–52 mg
Nucleotide phosphorus		2–3 mg
Oxygen (arterial)		17–22 vol%
Oxygen (venous)		11–16 vol%
pH	7.38–7.42	7.36–7.40
Pantothenic acid	6–35 μg	15–45 μg
Polysaccharides (total)	73–131 mg	
Protein (total)	6.0–8.0 g	19–21 g
Protein (albumin)	4.0–4.8 g	
Protein (globulin)	1.5–3.0 g	
Purines (total)		9.5–11.5 mg
Pyruvic acid	0.7–1.2 mg	0.5–1.0 mg
Riboflavin	2.6–3.7 μg	15–60 μg
Ribonucleic acid	4–6 mg	50–80 mg
Sphingomyelin	10–47 mg	150–185 mg
Thiamine	1–9 μg	3–10.7 μg
Urea	28–40 mg	20–40 mg
Urea N	8–28 mg	5–28 mg
Uric acid (male)	2.5–7.2 mg	0.6–4.9 mg
Vitamin A (caretenol)	15–60 μg	9–17 μg
Vitamin A (carotene)	40–540 μg	20–300 μg
Vitamin B_{12} (cyanocobalamin)	0.01–0.07 μg	0.06–0.14 μg
Vitamin D_2 (as calciferol)	1.7–4.1 μg	
Vitamin E	0.9–1.9 mg	
Water	93–95 g	81–86 g

Note: *Plasma* is the liquid portion of whole blood. *Serum* is the liquid portion of blood after clotting, the fibrinogen having been removed.



*Predominant, but not exclusive role.

Fig. 1. Basic components of blood.

of the embryo's second month of life, manifesting the second step in the erythrocytic series, erythroblasts are found in the liver and spleen. These cells are somewhat smaller and possess a smaller nucleus than the megaloblasts. At about the fifth month, centers of blood formation appear in the middle regions of the bones, with an accompanying progressive expansion of the marrow cavities. At this stage the marrow assumes nearly exclusively the function of producing the erythrocytes (red cells) required by the body — a process which continues throughout the life of the individual. At the time of birth, essentially all bone marrow is engaged in blood formation (not exclusively red cells). As the individual progresses toward maturity, much of the marrow of the long bones is converted into a fatty tissue in which blood cell formation (hematopoiesis) is no longer apparent. In adults, bone marrow active in the formation of blood cells is found in the ribs, vertebrae, skull, and the proximal ends of the humerus (upper arm) and femur (upper thigh).

Once erythrocytes enter the blood, it is estimated that they have an average lifetime of about 120 days. In an average person, this indicates that about 1/120th or 0.83% of the red cells are destroyed each day. At least three important mechanisms are involved in the death of erythrocytes: (1) Phagocytosis, defined as the ingestion of solid particles by living cells — in this case, by cells of the reticuloendothelial system. (2) Hemolysis by specific agents in the blood plasma. The erythrocytes are protected by a membrane. If this membrane is broken, the hemoglobin goes into solution in the plasma. Numerous substances (hemolytic agents) may cause this action and these include hypotonic solutions, foreign blood serums, snake venom, various bacterial metabolites, chloroform, bile salts, ammonia and other alkalis, among others. In this condition, the erythrocytes no longer can serve as oxygen carriers. (3) Mechanical damage and destruction, brought about by simple wear and tear as the reasonably fragile red cells circulate and recirculate through the body.

The stimulus for production of new red cells is provided by erythropoietin, a hormone that is apparently produced by the kidneys. The actual production is accomplished almost entirely by the red portions of the bone marrow, but certain substances necessary for their manufacture must be furnished by the liver. Surplus red cells, needed to meet an emergency, are stored in the body, mainly in the spleen. The spleen also breaks down old and worn red cells, conserving the iron during the process. See **Liver**; and **Spleen**.

When a sudden loss of a large amount of blood occurs, the spleen releases large numbers of red cells to make up for the loss, and the bone marrow is stimulated to increase its rate of manufacture of blood cells. When a donor gives a pint of blood, it usually requires about seven weeks for the body reserve of red corpuscles to be replaced, although the circulating red cells may be back almost to normal within a few hours. Repeated losses of blood within a short time, however, may easily deplete the red cell reserves.

In addition to hemoglobin, it has been found that there are least two other alternative oxygen carriers — hemerythrin and hemocyanin. In overall terms, as presently understood, these carriers are minor. Unlike hemoglobin, these two blood proteins do not incorporate an iron-porphyrin ring. The three blood proteins are strikingly colored in their oxygenated states — the familiar red of hemoglobin; the unusual reddish-tinted violet of hemerythrin; and the cupric-bluish color of hemocyanin. Klotz and colleagues (Northwestern University and other locations) have made a detailed study of the alternative oxygen carriers and suggest that an understanding of the three-dimensional structure of hemerythrin and of the electronic state of the active site is approaching, in refinement, that which is currently known about hemoglobin.

White Cells. There are several types of white cells, which are sometimes collectively called leukocytes, although some authorities reserve that term to identify only the granulocytes. White cells are irregular in shape and size, but generally are larger than the red cells. They differ from the red cells in that each white cell contains a nucleus. Adult humans have from 5000 and 9000 leucocytes per cubic millimeter of blood. In infants, the number is essentially doubled. There is roughly a ratio of 1 white to every 700 red cells. When white cells increase in number, the condition is called leukocytosis, a situation that is presented in pneumonia, appendicitis, and abscesses, among other conditions. A decrease in the number of leukocytes below normal is called leukopenia. In leukemia, there is an uncontrolled increase in the number of leucocytes.

In general terms, the white cells, each type with a specific function, accomplish the following actions: (1) Protection of the body from pathogenic organisms; and (2) participation in tissue repair and regeneration. Over the years, an increasingly detailed understanding of the white cells has occurred. These matters are described in some detail in the entry on **Immune System and Immunology**. Generally, whenever bacteria or other foreign substances enter the tissues, large numbers of white cells immediately travel through the walls of the blood vessels and to the site of disturbances. They take the bacteria and any other foreign materials into their own bodies, where they are digested. White cells are able to break up and carry away even as large an object as a splinter or thorn in the skin. They also help in carrying away dead tissue and blood clots that remain after a wound. Pus is largely composed of white cells that have been drawn to the infected area, as well as the dead and disintegrating tissue and bacteria. During severe infections, the white cells may be increased in the blood five- or tenfold. Because of this, a white cell count is made on the blood in order to confirm diagnosis in many infections.

Lymphocytes generally comprise between 25–30% of the white cells in human blood. These immunologically active cells are comprised of several classes, each of which has specific properties and functions. Lymphocytes are derived from stem cells located in the yolk sac and fetal liver. Later, some stem cells originate from the bone marrow. These cells then differentiate into lymphocytes in the primary lymphoid organs, principally the thymus and lymph nodes.

Monocytes (macrophages) are part of the mononuclear phagocytic system. They are large, mononuclear cells and comprise 3–8% of the leukocytes found in the peripheral blood. Monocytes originate in the bone marrow. When the mature cells enter the peripheral blood, they are called monocytes; when they leave the blood and infiltrate tissues, they are called macrophages. These cells play an important role in induction of the immune response. They present antigen to the lymphocytes that bear specific receptors for the antigen and also act as effector cells, attacking certain microorganisms and neoplastic cells.

Granulocytes contain specifically identifiable granules, including the neutrophils, eosinophils, and basophils. The neutrophils comprise 60–70% of all leukocytes in the blood. Neutrophils arise from precursors in the bone marrow and have a half-life of 4 to 8 hours in the blood, with about a day of life in the tissues. Neutrophils hasten to inflammatory sites by a number of different and poorly understood chemotactic (response to chemical stimulation) factors. Neutrophils have a marked capacity to phagocytize and destroy microorganisms. These cells also contain a number of degradative enzymes and small proteins. The cells are endowed with receptors for IgC and for a complement component (C3b). See also **Immune System and Immunology**. The eosinophils are named by virtue of the fact that the granules of cytoplasm are stainable with acid dyes, such as eosin. These cells are present in small numbers (2–4% of the blood), but under certain pathological conditions they show a marked increase. The exact function of eosinophils has been a mystery for many years. Some studies commenced in the mid-1970s have indicated a number of different functions. Many eosinophils have been found in tissues at sites of immune reactions that have been triggered by IgE antibodies (as found in nasal polyps or in the bronchial wall of some patients with asthma). Eosinophils have been found to contain several enzymes that can degrade mediators of immediate hypersensitivity, such as histamine, suggesting that they may control or diminish some hypersensitivity reactions. These cells have been found associated with infections caused by helminths (worms). The basophils are formed in the bone marrow and have a polymorphic nucleus. They occur only to the extent of about 1% of the leukocytes. The function of these cells is poorly understood. They are known to play a role in immediate hypersensitivity reactions and in some cell-mediated delayed reactions, such as contact hypersensitivity in humans and skin graft or tumor rejections and hypersensitivity to certain microorganisms in animals.

Platelets are the smallest of the formed elements of the blood. Every cubic millimeter of blood contains about 250 million platelets, as compared with only a few thousand white cells. There are about a trillion platelets in the blood of an average human adult. Platelets are not cells, but are fragments of the giant bone-marrow cells called megakaryocytes. When a megakaryocyte matures, its cytoplasm (substance outside cell nucleus) breaks up, forming several thousand platelets. Platelets are roughly disk-shaped objects between one-half and one-third the diameter of a red cell, but containing only about one-thirteenth the volume of the red cell. Platelets lack DNA and have little ability to synthesize proteins. When released into the blood, they circulate and die in about ten days. However, they do possess an active metabolism to supply their energy needs.

Because platelets contain a generous amount of contractile protein (actomyosin), they are prone to contract much as muscles do. This phenomenon explains the shrinkage of a fresh blood clot after it stands for only a few minutes. The shrinkage plays a role in forming a hemostatic plug when a blood vessel is cut. The primary function of platelets is that of forming blood clots. When a wound occurs, numbers of platelets are attracted to the site where they activate a substance (thrombin) which starts the clotting process. Prothrombin is the precursor of thrombin. Thrombin, in addition to converting fibrinogin into fibrin, also makes the platelets sticky. Thus, when exposed to collagen and thrombin, the platelets aggregate to form a plug in the hole of an injured blood vessel. Persons with a low platelet count (thrombocytopenia) have a long bleeding time. Platelet counts may be low because of insufficient production in the bone marrow (from leukemia or congenital causes, or from chemotherapy used in connection with cancer), among other causes. Also, individuals may manufacture antibodies to their own platelets to the point where they are destroyed at about the same rate they are produced. A major symptom of this disorder is purpura. Aspirin may aggravate this condition. See **Purpura**. The bleeding of hemophilia results from a different cause. See **Hemophilia**. Transfusion of blood is a major therapy used in treating platelet disorders.

Platelets not only tend to stick to one another, but to the walls of blood vessels as well. Obviously because they promote clotting, they have a key role in forming thrombi. As pointed out in the entry on **Arteries and Veins**, the dangerous consequences of thrombi are present in cardiovascular and cerebrovascular disorders. See **Cerebrovascular Diseases**; and **Ischemic Heart Disease**. Many attempts have been made to explain the process of atherogenesis, that is, the creation of plaque, which narrows arteries and, of particular concern, the coronary arteries. Recently, there has been increasing interest in the possible role of platelets in atherosclerosis. Evidence from experimentation with laboratory animals has provided some evidence of a role for platelets in this process. This is covered in some detail by Zucker (1980).

As reported by Turitto and Weiss (1980), red blood cells may have a physical and chemical effect on the interaction between platelets and blood vessel surfaces. Under flow conditions in which primarily physical effects prevail, it has been found that platelet adhesion increases fivefold as *hematocrit*[1] values increase from 10 to 40%, but undergoes no further increase from 40 to 70%, implying a saturation of the transport-enhancing capabilities of red cells. For flow conditions in which platelet surface reactivity is more dominant, platelet adhesion and thrombus formation increase monotonically as hematocrit values increase from 10 to 70%. Thus, the investigators suggest that red cells may have a significant influence on hemostasis and thrombosis; the nature of the effect is apparently related to the flow conditions.

Human von Willebrand Factor (vWF). In an excellent technical discussion, Ginsburg et al. review human factor VIII-von Willebrand factor. vWF is a large, multimeric glycoprotein that plays a central role in the blood coagulation system, serving both as a carrier for factor VIIC (antihemophilic factor) and as a major mediator of platelet-vessel wall interaction. Diminished or abnormal vWF activity results in von Willebrand's disease (vWD), a common and complex hereditary bleeding disorder. In the article, Ginsburg and colleagues describe how they have isolated a nearly full-length cDNA for human vWF and initial characterization of the vWF genetic locus. Such studies shed new knowledge on how the hemostatic system has evolved to minimize blood loss following vascular injury. In higher vertebrates, including humans, the system is complex and requires the interaction of circulating platelets, a series of plasma coagulation proteins, endothelial cells, and components of the vascular subendothelium. The initial and critical event in hemostasis is the adhesion of platelets to the subendothelium, a process that occurs within seconds of injury and provides a location for platelet plug assembly and fibrin clot formation.

Doolittle (1981), in an excellent paper on fibrinogen and fibrin, presents a detailed pictorial model of fibrinogen and develops the amino acid sequence of the fibrinogen molecule. In the paper, the author demonstrates how knowledge of the amino acid sequence of fibrinogen bolsters some long-standing notions about the protein's three-dimensional structure and general behavior. The sequence data complete a model in which two large terminal domains are connected to a central region by sets of three-strand ropes, giving rise to a trinodular structure similar to the one that electron microscopists proposed nearly 30 years ago. This extended polydomainal structure, as stressed by Doolittle, is exquisitely suited to a series of consecutive operations — polymerization, stabilization, and fibrinolysis — the first processes that stop bleeding and then clear away the clot to prevent blood vessel blockage. It is expected that this knowledge will be useful in helping patients whose blood tends to clot under the wrong circumstances.

Molecular Defects in Interactions of Platelets with Vessel Wall. As reviewed by J.N. George and colleagues (see reference), it was shown nearly a century ago that blood platelets are required for hemostasis. In that era, it was also learned that a congenital hemorrhagic disease can result from abnormal platelet functions. Over the years, many additional disorders of this type have been noted. Relatively recent analytical techniques have been used to identify the molecular abnormalities causing the defects and to define the mechanisms of platelet-vessel-wall interactions. It has been shown that platelet function requires specific receptors on the platelet surface that interact with macromolecules on the blood vessel wall, or with proteins in plasma. Some of these proteins are secreted by the platelet. George refers to these as "contact interactions." These reactions may include the adhesion of platelets to subendothelial tissue exposed at the cut end of a divided vessel, the recruitment of adjacent platelets to form a cohesive aggregate, and the generation of thrombin on the platelet surface to form the fibrin network that provides stability for the initial hemostatic plug.

Abnormalities in platelet function are placed by George and colleagues into four classes:

(1) Defects of platelet adhesion to subendothelium — these causing (a) the Bernard-Soulier syndrome, a rare, autosomal recessive trait which results in severe or even fatal hemorrhagic disease; (b) von Willebrand's disease, which presents mucocutaneous problems of bruising, epistaxis, and gingival bleeding; and (c) pseudo-von Willebrand's disease, in which platelets bind an increased amount of plasma vWF.

(2) Defects of platelet aggregation — these causing (a) Glanzmann's thrombasthenia and (b) congenital afibrogenemia.

(3) Defects of platelet secretory granules — the cause of gray-platelet syndrome.

(4) Defects in platelet coagulant activity.

Plasma. Normal blood plasma is a clear, slightly yellowish fluid, which is approximately 55% of the total volume of the blood. The plasma is a water solution in which are transported the digested food materials from the walls of the small intestine to the body tissues, as well as the waste materials from the tissues to the kidneys. Consequently, this solution contains several hundred different substances. In addition, the plasma carries antibodies, which are responsible for immunity to disease, and hormones. The plasma transports most of the waste carbon dioxide from the tissues back to the lungs. Plasma consists of about 91% water, 7% protein material, and 0.9% various mineral salts. The remainder consists of substances already mentioned. The salts and proteins are important in keeping the proper balance between the water in the tissues and in the blood. Disturbances in this ratio may result in excessive water in the tissues (swelling or edema). The mineral salts in the plasma all serve other vital functions in the body and must be supplied through diet. See Table 2.

Some of the blood plasma, as well as some of the white cells, filters through the walls of the blood vessels and out into the tissues. This filtered plasma (lymph) is a clear and colorless fluid that returns to the blood through a series of canals referred to as the lymphatic system. This system contains filters (lymph nodes) which remove bacteria and other debris from the lymph. These nodes, especially those located in the neck, armpit, and groin, may become swollen when an infection occurs in a nearby site. Blood clots do not occur normally while the blood is in the vessels. But in an injury, one of the plasma proteins (fibrin) forms a mesh in which the blood cells are trapped, and this mesh is the clot. Blood serum is the yellowish fluid left after the cells and fibrin have been removed from the blood.

Blood Osmotic Pressure. The presence of solute molecules and ions in relatively high concentrations in blood establishes an osmotic pressure,

[1] A hematocrit is a tube calibrated to facilitate determination of the volume of erythrocytes (red cells) in centrifuged, oxalated blood, expressed as corpuscular volume percent.

TABLE 2. INORGANIC CONSTITUENTS OF HUMAN PLASMA OR SERUM

Constituent	Value/100 ml
Aluminum	45 μg
Bicarbonate	24–31 meq/liter
Bromine	0.7–1.0 μg
Calcium	9.8 (8.4–11.2) mg
Chloride	369 (337–400) mg
Cobalt	10 (3.7–16.6) μg
Copper	8–16 μg
Fluorine	109 (75–145) μg
Iodine, total	7.1 (4.8–8.6) μg
Protein bound I	6.0 (3.5–8.4) μg
Thyroxine I	4–8 μg
Iron	105 (39–170) μg
Lead	2.9 μg
Magnesium	2.1 (1.6–2.6) mg
Phosphorus, total	11.4 (10.7–12.1) mg
Inorganic P	3.5 (2.7–4.3) mg
Organic P	8.2 (7–9) mg
ATP P	0.16 (0–6.4) mg
Lipid P	9.2 (6–12) mg
Nucleic acid P	0.54 (0.44–0.65) mg
Potassium	16.0 (13–19) mg
Rubidium	0.11 mg
Silicon	0.79 mg
Sodium	325 (312–338) mg
Sulfur	
Ethereal S	0.1 (0–0.19) mg
Inorganic S	0.9 (0.8–1.1) mg
Non-protein S	2.8 (2.4–3.6) mg
Organic S	1.7 (1.4–2.6) mg
Sulfate S	1.1 (0.9–1.3) mg
Tin	4 μg
Zinc	300 (0–613) μg

which tends to transport water from the exterior, through the semipermeable membranes of the blood vessel walls, into the bloodstream. This osmotic transport of water inward is opposed by the effect of hydrostatic pressure within the blood vessels, tending to force water (and soluble substances) out through the capillary walls. The loss through leakage of some of these solutes is indirectly restored through the action of the lymphatic system. Among the blood constituents important in maintaining blood osmotic pressure (and thus helping to regulate the volume of fluid in the blood) are the blood proteins. Among these, the protein fraction termed albumins, being relatively low in molecular weight, makes the greatest contribution to the total osmotic effect.

Blood Processing and Transfusion Therapy

Blood transfusion practice has changed markedly in recent years. At one time, units of whole blood were administered to patients with a variety of requirements stemming from different conditions. These conditions ranged from acute blood loss (hemorrhage, bleeding from injuries, etc.) to aplastic anemia, among other blood-related problems.

The outer portion of the erythrocyte (red cell) is a very complex material composed of proteins, polysaccharides, and lipids, many of which are antigens, sometimes referred to as blood group substances. The presence of most, if not all, of these antigens is genetically determined, and their number is such that there may be few, if any, individuals in the world with an identical set of antigens on the red cells — monozygotic twins excepted. These differences in whole blood were learned early in the development of transfusion technology. Fundamental to the refinement of the technology was the discovery by Karl Landsteiner (Nobel Prize winner in 1930) for his observations of the four hereditary blood groups. Landsteiner developed the ABO blood-typing system, which serves as a principal guideline in determining the suitability of donors and recipients. This system consists of three allelic genes, dividing all humans into four groups, A, AB, B, and O. In a few rare individuals, the presence of a suppressor gene may prevent the expression of the A, B, O group character. The products of these genes are the A, B, and O antigens or substances. These antigens not only are located on red cells, but are widely distributed in the body, occurring in the endothelium of capillaries, veins, and arteries, and in numerous cells throughout the body. In addition to a cell-associated form, these antigens occur in soluble form in many body fluids, such as the saliva, gastric juice, urine, amniotic fluid, and in very high concentrations is pseudomucinous ovarian cyst fluid. All individuals possess cell-associated A, B, and O antigens. The presence of the soluble form, however, is governed by a recessive gene called the secretor gene, which exists as two alleles, *Se* and *se*. Individuals who possess at least one *Se* gene secrete the antigens, while those with two se genes do not. The A, B, and O antigens are not uniquely human, but are quite widely distributed in nature. They are found on primate erythrocytes and in the stomach lining of pigs and horses. Intensive investigation has produced considerable information concerning the chemical composition of these antigens. They are extremely stable substances, which is attested by the fact that they can be extracted from Egyptian mummies, thus making it possible to obtain the blood groups of this ancient people. Specific antigenic activity is associated with the carbohydrate moiety, and since the A, B, and O substances possess the same four sugars, the difference between them lies in their arrangement. Analysis of purified A, B, and O substances reveals that about three-fourths of the weight is accounted for by four sugars: L-fructose, D-galactose, *N*-acetyl-D-glucosamine, and *N*-acetyl-D-galactosamine. The remainder consists of amino acids. See **Immune System and Immunology**.

Cross-Matching. Upon receipt of a tube of clotted blood at a blood bank for typing and cross-matching, procedures are undertaken to determine which antigens are on patient's red cells and which antibodies against red cell antigens are present in the patient's serum. Typing is routine for red blood cell antigens in the ABO system and for a single specificity in the Rh system, namely, the D phenotype.

The Rh group, so denoted because the antigen was first found in the red cells of Rhesus monkeys, is very complex, consisting of perhaps 20 antigens. The Rh_0D antigen is the most important of these antigens because of its possible involvement in the induction of *hemolytic disease of the newborn*. Today, Rh_0D immune globulin (RhoGam® and Gamulin-Rh®, among others) is available to alleviate this danger. This danger is brought about when an Rh-negative woman and an Rh-positive man have an Rh-positive child. There is the grave risk that the woman will become sensitized to the Rh factor in her infant's blood and begin to produce anti-Rh antibodies. The first child is not usually affected, but with subsequent pregnancies, the mother may send sufficient damaging antibodies into the child's blood to threaten its life. When this occurs, in the absence of using the Rh_0D immune globulin, an exchange blood transfusion with almost complete replacement of the infant's blood by Rh-negative blood of the proper ABO group is necessary.

Component Therapy. Frequently, patients do not require all of the blood components and, in fact, their presence can cause many problems. From experience with whole blood therapy over a number of years, *component therapy* emerged. In component therapy, which has many advantages, the patient is given specifically what is needed by way of blood components. Further, separate blood fractions can be stored under those special conditions best suited to assure their biological activity at the time of transfusion. Component therapy also avoids the introduction of foreign antigens and antibodies. It is seldom that fresh whole blood is the treatment of choice providing that specific components are readily available within the time needed.

Processing of Donor Blood. When donor blood is received at a processing center, it is first tested for syphilis and hepatitis B antigen. One unit of whole blood is 500 milliliters. It is then separated into: (1) a unit of *packed erythrocytes* (volume of 300 milliliters and hematocrit value of 70 to 90); this substance is storable in citrate-phosphate-dextrose at 4 °C (39.2 °F) for up to 3 weeks; (2) a unit of *platelets* (packet) with a volume of 50 milliliters containing about 80 billion platelets). This substance is storable (while being gently mixed) at room temperature for 2 or 3 days. (3) A unit of *cryoprecipitate* (volume of about 10 milliliters containing from 80 to 120 units of Factor VIII and from 300 to 400 milligrams of fibrinogen). This substance is stable in a frozen condition for about one year. (4) One unit of *plasma* (a volume of about 200 milliliters, from which about half of the fibrinogen has been removed). This substance contains platelets, Factor VIII, as well as all remaining procoagulants, albumin, salt, and antibodies that were a part of the original plasma. This substance may be (a) stored in the frozen state, (b) refrigerated, or (c) further processed for individual globulin classes and albumin.

Thus, somewhat analogous to obtaining specific drugs for different conditions, the physician can order up specifically those blood components

required for a given need. Platelets, which survive poorly in whole blood stored in acid-citrate-dextrose solution under refrigeration, can be obtained in platelet packets as previously mentioned, or as washed platelets. Factor VIII, for the management of hemophilia, can be obtained in a lyophilized or other purified form. In whole blood, by contrast, procoagulants stored in whole blood decay so that, after a few days, the availability of Factor VIII and other allied components is extremely low. As the result of additional processing, blood centers can furnish prothrombin complex concentrate (*Proplex*), each batch bearing a specific analysis. Preparations of peripheral white blood cells are available from centers with specific blood processing equipment. Additionally, substances for expanding plasma volume, such as fresh frozen plasma, albumin solutions, and Dextran, among others, are available.

Frozen Red Cells. In the early 1950s, the concept of using previously frozen red cells was considered to be one of great potential for the medical profession. One early assumption was that infectious agents would not be passed on because of their destruction by the freezing process. This was disproved in 1978, however, when it was demonstrated that hepatitis B virus was not rendered noninfectious by such processing. The unique contribution of the freezing technology was claimed to be the ability to guarantee the availability of rare blood types for transfusion to recipients who were sensitized to single or multiple high-frequency red-cell antigens. Storage at $-80\,^{\circ}C$ made it possible to stockpile such blood for approximately 3 years, but no more than 10 years. Unfortunately the shelf life of a thawed deglycerolized unit was only about 24 hours. As reported by Chaplin, it was predicted that the future large-scale use of previously frozen red cells would depend mainly on the superiority of the product in broad areas of transfusion practice, and secondarily on simplifying the technology, reducing the cost, and extending the post-thawing shelf life. The declining use of previously frozen red cells over the intervening years reflected a lack of progress on all fronts.

Statistics indicate that in late 1978, the American Red Cross reported a demand for thawed, deglycerolized human red cells of nearly 100.000 units per year. By May 1983, the demand was only approximately 42.000 units. Thus, it now appears that the need for frozen red cells was mainly found in filling rare donor blood types. Chaplin summarizes — future developments may yet prove previously frozen red cells to be the sleeping giant of red-cell replacement therapy; for the present, we must be content with the minor but crucial role in which they have proved their worth beyond doubt.

Impact of AIDS on Blood Supply. Acquired immunodeficiency syndrome was first diagnosed as a specific disease entity in 1981 and, by 1983, health officials were aware that the disease could be transmitted via infected blood. In the spring of 1985, kits became available for testing blood for antibodies to the AIDS virus. Since then, virtually all official and approved blood bank organizations have used the test for screening donated blood. Prior to invoking this test, the Centers for Disease Control (Atlanta, Georgia) estimated that well over 400 people had developed AIDS because they received infected blood or blood products. It was later estimated by the CDC that the persons so infected represented less than 2% of persons who had developed AIDS. **See Acquired Immune Deficiency Syndrome**.

A major drawback of the ELISA (enzyme-linked immunosorbent assay) test is that it will sometimes indicate a positive result even though an individual may not be infected with the AIDS virus. The test has since been refined and improved. It is the normal practice of blood bank operators to make three ELISA tests on a blood sample before rejection. A more accurate test, known as the Western blot test, may then be used. This latter test is much more likely to be antibody-positive due to infection by the AIDS virus. It should be noted that the ELISA test can, but rarely, yield a "false negative" result. Timing is also a factor. Persons who are in very early stages of AIDS infection may not contain detectable levels of antibodies simply because their immune system has not had sufficient time to produce the antibodies. A celebrated case along these lines occurred in Colorado in 1986 — where a newly infected person was not positively detected as having AIDS and the blood was used for transfusion in two patients. One of the persons contracted AIDS, and the infection was attributed to that particular transfusion.

The proposed use of *autologous* blood where an individual places blood in a bank for possible future personal needs has received mixed reactions among the professionals. There is general agreement that this is a good procedure where pre-operative knowledge of surgery is established, but for long-term storage, many authorities feel that the procedure is logistically impractical. The public media have thoroughly explored the psychosocial implications of the AIDS virus relationship to the national blood supply.

Blood Transfusion and Athletics. At the time of the 1984 Los Angeles Olympic games, it was reported that 7 members of a 24-member cycling team, including 4 medalists, had received blood transfusions in an effort to enhance their performance. Team officials report that the athletes were given transfusions of whole blood, collected from both relatives and from unrelated donors, in a motel room. The initial public reaction was negative and cries for disqualification were heard. The medical profession spoke out forcefully against the practice. Be that as it may, Klein (see reference) asks some interesting questions: Do blood transfusions afford world-class athletes a substantial competitive advantage? Is the practice safe? Is it ethical to use blood as a recreational drug? It has been well established, including a test conducted over 50 years ago, that the capacity to perform sustained muscular activity depends on the ability to transport oxygen to the contracting muscle cell. Relating exercise capacity to the maximal oxygen uptake is a widely accepted measure of physical fitness. Transfusion increases oxygen delivery to exercising muscle by increasing the amount of the carrier protein hemoglobin. Red-cell mass and maximal oxygen uptake are generally well correlated. Thus, as reasoned by Horstman et al. (1976), if the metabolic limit of muscle is not exceeded, an increase in the hemoglobin concentration should result in increased oxygen consumption and muscle performance. The elevated hemoglobin concentration induced by hypoxia is one rationale for the widely accepted technique of high-altitude endurance training. This training increases the oxidative capacity of muscles as well. Thus, transfusion would seem least likely to benefit the sprinter, whose muscles generate energy primarily by anaerobic metabolism, and most likely to benefit endurance athletes, whose work capacity depends on a ready supply of transported oxygen. In a 1980 test by Buick et al., of the re-infusion of autologous red cells (previously frozen and stored) in subjects, with the elevation of the circulating red-cell mass as 1 g per deciliter above control values; this resulted in improved treadmill endurance, a lower heart rate during exercise, and less accumulation of blood lactate, all measures which contribute to performance. There was a mean overall increase in maximal oxygen uptake of only 5%. One conclusion that may be drawn — red-cell infusions can improve performance of world-class athletes, but the advantage may be slight.

The general conclusions are aptly expressed by Klein — blood is a drug. Collection, storage, and compatibility testing of blood for transfusion are carefully prescribed by the Food and Drug Administration in the United States and by similar organization in a number of countries. Facilities for blood collection and transfusion are registered, licensed, and inspected for compliance. Like other drugs, blood should be given only for medical indications. As early as 1976, the Medical Commission of the International Olympic Committee formally condemned the practice of blood transfusion for athletes in good health. It has been suggested that even stronger regulations should be formulated.

Blood Substitutes. Researchers in Japan (Fukushima Medical Center) and in other institutions in Europe and North America have been investigating substances that, in major characteristics, may serve as a substitute for blood, particularly in emergency situations where rare blood types are not immediately available to severely ill patients who require transfusions. For example, in early 1979, a Japanese patient with a rare O-negative blood was given an infusion of one liter of a new, oxygenated perfluorocarbon emulsion. This compound carried oxygen through the patient's circulatory system until the rare blood could be obtained. Later that year, eight additional patients survived infusions with artificial blood. As early as 1966, investigators at the University of Cincinnati demonstrated that life could be sustained when rodents were immersed in perfluorochemicals for long periods. This class of chemicals can dissolve as much as 60% oxygen by volume, as contrasted with whole blood (20%), or salt water or blood plasma (3%). Initially, a major problem existed because pure perfluorochemicals are not miscible with blood. In the late-1960s, researchers (University of Pennsylvania; Harvard School of Public Health) demonstrated that perfluorochemicals could be emulsified. Research is continuing along these lines. Also, new chemicals of this class are being sought. Initially, the research was done with perfluorobutyltetrahydrofuran and perfluorotripopylamine, both superior carriers of oxygen, but prone to concentrate in some organs of the body, notably the liver and spleen. In

1973, perfluorodecalin was found to be completely eliminated from the body. The approach in Japan has differed somewhat, in that research has been directed to add other chemicals that will increase the half-life of the chemicals in the body.

Reports show the synthesis of artificial red cell prototypes that meet the six essential specifications for such cells are: (1) the micro-capsule membrane must be biodegradable and physiologically compatible; (2) the encapsulation process must avoid significant hemoglobin (Hb) degradation; (3) when encapsulated, the oxygen affinity of Hb must be reduced relative to that of free human Hb; (4) the encapsulated Hb must be sufficiently concentrated, that is, more than 33% of that in erythrocytes; (5) there should be no evidence of overt intravascular coagulopathy; and (6) the artificial cells must be small enough to pass unrestricted through normal capillaries. These prototypal artificial red cells are called *neohemocytes* (NHC). The researchers point out that a nontoxic resuscitation fluid that combines the functions of a plasma expander with the ability to carry and deliver oxygen to tissues could prove useful in treatment of trauma, as a temporary substitute for red cells, and for the treatment of tissue ischemia.

Blood Recycling. In a process known as *autotransfusion*, introduced in the early 1980s, blood lost during operative procedures, particularly in heart surgery, is recycled back to the patient. Some reports indicate the need for donor blood can be reduced by as much as 60%. Instead of discarding blood lost during surgery, as has been the traditional practice, the blood is collected in a plastic bag with a special filter to cleanse impurities before the blood is returned to the patient. The procedure has many advantages, including costs of transfusion and elimination of risks from hepatitis, errors in mismatching blood types, and other complications that may arise with donor blood. Although results appear to be positive thus far, a few additional years may be required before the procedure is fully accepted as standard practice.

Blood as an Indicator of Disorders and Diseases

Since the blood performs many services for all parts of the body, it will reflect disturbances that occur as the result of many widely divergent diseases. This had led to the development of a variety of blood tests, either to confirm a diagnosis or to follow the effectiveness of treatment in the patient. *Immunological* or *serological* tests are performed to confirm the diagnosis of selected types of infectious diseases, and are based upon the principle that in certain diseases there appear in the blood specific substances (antibodies) which are produced by the body in resisting invasion by specific disease-producing media. One of the more widely used tests is the Kolmer test for syphilis. Blood typing tests are also serological in nature. A second group of blood tests are known as *hematological*. These tests determine the number of each type of circulating blood cell (*blood count*), the total volume of red cells in a blood sample (*hematocrit*), and the hemoglobin content of the blood. A *differential* blood count is one in which selected dyes are used to distinguish better the different kinds of white blood cells. These tests are important in diagnosing and treating illnesses, such as infections, the anemias, and the leukemias.

Another group of blood tests involves *bacteriological* techniques. Blood and bone marrow samples are obtained under aseptic precautions and introduced into a variety of artificial culture media, with subsequent isolation and identification of the specific microorganism responsible for the illness. Relative susceptibility of the specific strain of bacteria to the available chemotherapeutic and antibiotic agents may then be determined and the effectiveness of such agents in sterilizing the blood-stream can be determined by further blood cultures.

Many *chemical* tests are performed on blood samples to determine the quantitative relationships between circulating globulins, albumin, sugar, non-protein nitrogen, minerals, and other normal and abnormal constituents. Such chemical tests are important in diabetes, kidney diseases, the failing heart, and in pancreatic and liver diseases. In all of these disorders, pronounced changes in the relative amounts of the various chemical constituents of the blood occur. Chemical tests also may be performed on urine, spinal fluid, and saliva for some special purpose, and since most of these fluids are derived from the blood plasma, their chemical analysis frequently reflects changes in the blood itself. During prolonged therapy with certain drugs, it may be desirable to measure chemically the concentration of the drug in the blood plasma.

Sophisticated instrumentation and procedures are used in research involving blood and its functions. Phase contrast microscopy has the advantage that living cells can be studied for long periods of time; chromatin, mitochondria, centrosomes and specific granules can be seen and photographed at magnifications of $2{,}500\times$. The method is excellent for the study of granules of the matrix of cells which is unseen in traditionally fixed and stained cells. It is an excellent aid for those who wish to use the electron microscope, because areas demonstrated by light can be compared with those visualized by the electron beam. The study of blood by motion pictures (*microcinematography*) has been used for many years. With the invention of the phase microscope, this approach to the study of blood cells has been an important tool. Studies of the movements of the lymphocytes in rats showed a softening of the membrane at the forward moving end, and pseudopod formation; contractions of the cell force the inner plasma forward, while the external plasma gel remains fixed except at the posterior end, then it becomes softer and passes through the stiffer ring of plasma gel to become more gelated at the anterior end. This is an example of the type of detailed investigation that can be made with microcinematography. Using speed photography at 3,200 frames per second, the red blood cell has been observed to have an interior velocity of $30\times$ that of water at $38\,^{\circ}$C. In the dog's mesentery, red blood cells passing into capillaries from larger arterioles take the form of an inverted cap or parachute; when blood flow is stopped, they become biconcave disks. The cup shape is suggested as bringing more surface close to the capillary endothelium.

Other blood research techniques include the use of physical and chemicals agents, ultracentrifugation, cytochemical methods, microincineration, and autoradiography.

Occult Blood as an Indicator of Cancer. A good number of physicians encourage asymptomatic patients who are over 40 to undergo annual testing for occult blood in stool as part of a screening program, with the hope that colon cancers may be detected at an early, curable stage or that adenomatous polyps may be found and removed in an attempt to prevent cancer. This concept remains controversial and is unproven, but because it is noninvasive and simple and relatively low in cost, many physicians regard the test as quite useful. Sampling errors do occur. The test is not always positive with patients who have colon cancer because some cancers do not bleed, or bleed intermittently. Vitamin C may inhibit the oxidation of guaiac (a colorless phenolic compound that is converted into a colored quinone when contacted by hemoglobin). Some stools may yield a positive result when fresh, but a negative result after drying on the *Hemoccult* card. Also, the test can be positive when colon cancer is not present — the result caused by bleeding from some other lesion, such as salicylate gastritis or hemorrhoids. Dietary substances (red meat, uncooked peroxidase-rich vegetables, elemental iron, etc.) may cause a "false positive" result. Persons undergoing such screening are directed to avoid red meat in their diet for several days prior to the test.

More recently, a new test (*HemoQuant*) has been developed. This test involves the chemical conversion of stool heme to porphyrins that can be assayed fluorometrically. The test also detects porphyrins present in stool as a result of bacterial and enzymatic degradation of hemoglobin as it travels through the intestines. Thus, this new test provides a quantitative measure of all blood that enters the gastrointestinal tract. It appears to be biochemically sound and is considered a methodological breakthrough.

BLOOD-BRAIN BARRIER. Many blood-borne solutes do not penetrate into central nervous tissue as rapidly as they penetrate into other tissues. First discovered by P. Ehrlich in 1885, certain aniline dyes, when injected into the bloodstream of mice, stained most tissues of the body rapidly, but left the nervous system largely uncolored. During the ensuing half-century, the slow permeation of the brain by dyes and other histologically identifiable substances (e.g., ferricyanide and silver) was studied intensively. When these materials were placed in the cerebrospinal fluid, they entered the brain without restriction by passive diffusion through the pial surface. These observations gave rise to the erroneous concept that all metabolic exchange between blood and brain occurred via the cerebrospinal fluid. It is recognized, of course, that metabolite transfer actually occurs throughout the central nervous system vasculature, but is subject to local controlling mechanisms not found in other tissues.

Radioisotopes enabled the study of rates of exchange for many physiologically significant substances and, with few exceptions, the exchange of blood-borne solutes with the central nervous system has been found to be significantly, often orders of magnitude, slower than with other tissues. Certain metabolites and metabolic products such as glucose, oxygen, and carbon dioxide, as well as lipoid soluble substances and water itself, move rapidly between the blood and extravascular fluids of the central nervous system, but inorganic ions and most other highly dissociated compounds are very slow to equilibrate.

In attempting to evolve a general theory, the most persistent approach has been the attempt to discover physicochemical properties of molecules that determine these rates of migration. This led variously to explanations based upon electric charge, molecular size, dissociation constant, protein binding, lipoid solubility, and combinations of these. Selected series of compounds can be found which behave quite predictably according to one or more of these criteria. There is considerable similarity between blood-brain barrier permeability and cell membrane permeability, and it appears that solutes, to pass from the plasma to the extravascular fluids of the central nervous system, must for the most part pass through and not between cells.

The functional significance of the blood-brain barrier mechanism is to buffer the neuronal microenvironment against changes in plasma concentrations of various important solutes and to regulate the composition of the neuronal "atmosphere" for optimum performance.

If the brain were exposed to the normal fluctuations which occur in the blood after meals, exercise, etc., the result would undoubtedly be uncontrolled nervous activity because some hormones and amino acids serve as neurotransmitters and potassium ions influence the threshold for the firing of nerve cells. Hence, the brain must be kept rigorously isolated from transient changes in the composition of the blood. Yet, if the isolation were complete, the brain would die for lack of nourishment. Fortunately, the essential nutrients traverse the blood-brain barrier easily, helped across by transport systems that recognize specific molecules and carry them into the brain. There appear to be several different types of transporter, each of which has a specific function.

An essential feature of the brain-vascular capillary interface is that the endothelial cells of the capillary are joined by what is known as a continuous tight junction where the outer lipid-based leaflets of the two adjoining cells merge. Also, the brain capillaries are almost completely surrounded by astrocytes, long slender extensions of brain glial cells that, among other functions, form the myelin that sheathes some neurons. The exact function of the astrocytes is still being debated.

The most decisive factor in molecular penetration of the blood-brain barrier is lipid solubility; where this is high, the molecules readily breach the barrier. On the other hand, where water solubility is high, they tend not to be taken up by the brain. Yet, in order to function, the brain needs non-lipid soluble substances, such as glucose, and these appear to be brought into the brain substance by specific "transporter" molecules residing in the endothelium of the brain capillaries. Such transporter molecules are asymmetric, transporting in one direction only — inward to the brain substance to supply wanted nutrients, or outward to the capillaries to eliminate waste products.

Recent work has indicated that the blood-brain barrier may also be hormonally regulated. It has long been known that the pituitary and pineal glands and part of the hypothalamus do not possess blood-brain barriers, but now it appears, at least in adrenalectomized rats, that the pituitary-adrenal axis may physiologically modulate the permeability of the brain vasculature. See also **Central and Peripheral Nervous Systems**.

BLOOD CLOTTING: GENERAL PATHWAY. Hemostasis is the process that maintains blood in a fluid state while retaining the capacity to respond to injury by forming a clot to stem blood loss. This process comprises a complex interplay between circulating and cellular proteins which regulate the formation of fibrin and the fibrin/platelet hemostatic plug at the site of injury, and defects in the individual proteins can lead to bleeding disorders (hemophilia). Several of the proteins that participate in hemostasis require vitamin K for function, and inhibition of vitamin K action is commonly used in anticoagulant therapy. See also **Hemophilia**.

Overview of the Blood Clotting Pathway

Circulating blood is normally maintained in a fluid state; however, a hemostatic system exists ready to respond explosively to injury by plugging the wound to stop blood loss. This remarkable process, called *hemostasis*, comprises a complex orchestration of events. The individual components are proteins that work in combination to respond quickly, to restrict the clot to the site of injury, and to down regulate their action once the clot is formed. Three different types of proteins participate in a series of reactions to generate a clot: enzymes, cofactors and inhibitors. Enzymes are proteins that catalyze a chemical reaction, processing many molecules of the substrate that they act upon. Cofactors interact with enzymes to increase the efficiency of the reaction. Inhibitors interfere with a reaction. See also **Enzyme**.

The series of reactions that gives rise to a clot is shown in Figure 1. Hemostasis is initiated by the enzyme factor VIIa and its cofactor tissue factor. Factor VIIa is the activated form of factor VII and the activation event is an important component of coagulation. The clotting factors normally circulate as inactive forms which are activated by cleavage of the molecule during coagulation. Most of the clotting enzymes are proteases which carry out the cleavages. Once a clotting enzyme is activated, it then acts as a protease to cleave and activate a different clotting factor. A trace amount of factor VIIa circulates in blood and may be the source responsible for triggering coagulation, possibly by autoactivation of factor VII to factor VIIa (Fig. 1). Factor VIIa then activates many molecules of factor X to factor Xa, which activates even more molecules of prothrombin to thrombin, and thrombin then converts fibrinogen to fibrin. This stepwise activation of enzymes is referred to as the coagulation cascade: each of these reactions is amplified at every step, facilitating the rapid response of the body to injury. Most of the enzymes in the coagulation pathway require a cofactor: factor VIIa uses tissue factor, factor IXa requires factor VIIIa and factor Xa uses factor Va. Tissue factor resides on the surface of certain cell types, while factor VIII and factor V circulate in blood as inactive forms that become bound to a cell surface and activated during coagulation. In the absence of these cofactors the reactions proceed poorly, and so the individual cofactors are critical for efficient clotting. See also **Proteases**.

Clot formation occurs at a cell surface. Normally the vessel wall is composed of a continuous protective barrier of endothelial cells (the endothelium, Fig. 2). The endothelium does not react to circulating clotting factors. However, when the endothelium is injured and the subendothelium exposed, the cofactor tissue factor present on the surface of cells in the subendothelium now binds to the enzyme factor VIIa to initiate clotting and the series of reactions that generates fibrin (Figs. 1 and 2). Once fibrin is formed, this unusual molecule polymerizes to generate a mesh-like network that holds the platelets together in the hemostatic plug (Fig. 2).

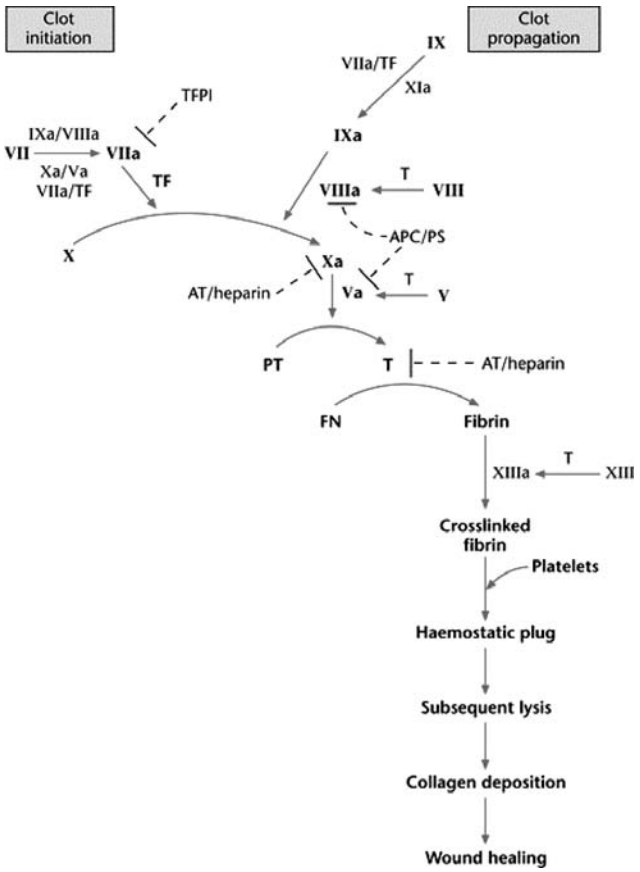

Fig. 1. Clot formation. Fibrin generation involves a series of consecutive activation events, where inactive proteins are converted to active ones after cleavage by enzymes called proteases. Each activation results in the generation of a new protease which now acts on a subsequent protein, in a cascade-like fashion, that ultimately produces fibrin. Most of these proteases require cofactors to function. Anticoagulants (e.g. protein C and protein S) act to turn off coagulation. The targets for these inhibitors are indicated by a dashed line. The fibrin clot is transitory and eventually disappears. Clot dissolution proceeds by a complex process called fibrinolysis, followed by remodeling of the endothelium to restore the tissue to its original state. Enzymes: VII, factor VII; VIIa, activated factor VII; IXa, activated factor IX; Xa, activated factor X; XIa, activated factor XI; XIIIa, activated factor XIII; APC, activated protein C; PT, prothrombin; T, thrombin. Cofactors: Va, activated factor V; VIIIa, activated factor VIII; PS, protein S; TF, tissue factor. Inhibitors: AT, antithrombin; TFPI, tissue factor pathway inhibitor. FN, fibrinogen.

The fibrin network is strengthened by the formation of cross links between different fibrin molecules, which is effected by the enzyme factor XIIIa. The platelets and fibrin are adhered to each other and to the subendothelium by adhesion molecules called integrins. Circulating platelets exist in a resting state but are activated when they become part of the haemostatic plug. Activation occurs, for example, when thrombin generated at the site of injury binds to receptors on the platelet surface to signal intracellular events. Once activated, the platelets undergo several physiological changes, for example integrin activation promotes adhesion or membrane changes that promote generation of fibrin. See also **Platelets**.

Hemostasis has redundancy built into the system. For example, factor IXa is generated both by factor VIIa/tissue factor and by factor XIa, and factor Xa is generated both by factor VIIa/tissue factor and by factor VIIIa/factor IXa (Fig. 1). The factor VIIa/tissue factor reaction was historically referred to as the extrinsic pathway because tissue factor is extrinsic to circulating blood (Fig. 2). The generation of factor Xa through a pathway involving factor XIa activation of factor IX, followed by factor IXa/factor VIIIa activation of factor X was referred to as the intrinsic pathway. The importance of factor VIIa/tissue factor to coagulation was obscured for a long time: hemophiliac patients deficient in the production of either factor VIIIa or factor IXa have severe bleeding complications, showing the critical importance of these two proteins to hemostasis. In contrast, factor VIIa-deficient patients have variable bleeding responses.

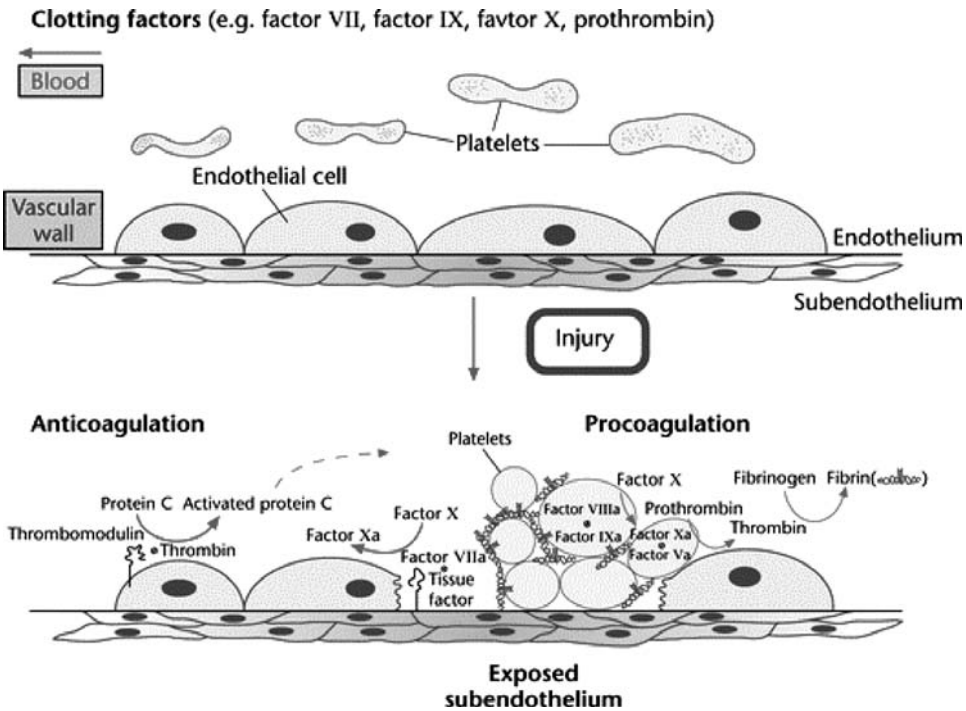

Fig. 2. The hemostatic response to injury. When the endothelium is disrupted by injury, tissue factor (which is not present on platelets, or on endothelial cells under normal physiological conditions) is exposed to factor VIIa to initiate the complex series of reactions, described in Figure 1, which give rise to fibrin. The fibrin monomer, which is composed of three different proteins, undergoes polymerization and binds with platelets to the subendothelium to form a haemostatic plug, called the thrombus. Platelets normally circulate in a resting form but are activated at the site of injury, releasing many different chemicals from granules inside the cell (indicated here as grains in the circulating platelets) which are important to platelet adhesion, aggregation and coagulation. Clot formation is restricted to the site of injury by a number of regulatory mechanisms. One example shown here is the activation of protein C on endothelial cells located away from the site of injury. Details for the reactions are described in the text.

None the less, a more thorough understanding of the process of hemostasis has developed so that it is now commonly accepted that factor VIIa and tissue factor initiate coagulation, while factor VIIIa and factor IXa are required for clot propagation (Fig. 1). Clot initiation and propagation occur on different cell surfaces (Fig. 2). While platelets are responsible for most of the clot propagation, these cells do not have tissue factor for initiating coagulation. Thus, the coagulation pathway (Fig. 1) involves the interplay between at least two cell types for the generation of large amounts of fibrin. See also **Blood Coagulation**.

Regulation of Clotting

The coagulation pathway involves several feedback reactions which accelerate the formation of a clot. For example, once prothrombin is activated to thrombin, thrombin activates factor V to factor Va and factor VIII to factor VIIIa (Fig. 1). These two activated cofactors then accelerate the generation of even more thrombin. Another example of feedback is that factor Xa and factor IXa, once formed, generate more factor VII to factor VIIa. Since factor VII activation is the first step in coagulation, all subsequent reactions will be amplified by the coagulation cascade, accelerating the whole hemostatic process.

Two important regulatory features built into hemostasis are the abilities to restrict clot formation to the site of injury and to turn the coagulation process off once the hemostatic plug has been formed. Such regulation is critical for several reasons. For example, if the growth of the hemostatic plug was unlimited it would eventually block the artery and obstruct blood flow. Continuous coagulation would also lead to the total consumption of the circulating clotting factors, leaving the body unprotected if exposed to additional injury. Finally, restricting coagulation to the site of injury prevents circulating activated factors from causing thrombus formation at undesirable sites, like capillaries where even a very small clot would block blood flow. See also **Thrombosis**.

One mechanism that restricts clot formation to the site of injury is the ability of thrombin to activate the cofactors factor V and factor VIII only at this site. These two proteins are activated on the surface of platelets within the hemostatic plug but not on circulating platelets (Fig. 2). Another regulatory mechanism that serves to dampen coagulation is a negative feedback mechanism that occurs if thrombin escapes from the site of injury. Uninjured endothelial cells contain a cofactor on the cell surface called thrombomodulin. This protein binds circulating thrombin and this complex then activates protein C (Fig. 2). Activated protein C then binds to its cofactor protein S and inactivates factor VIIIa and factor Va, shutting down the coagulation cascade (Fig. 1). Protein S and activated protein C are consequently referred to as anticoagulants.

Another mechanism for restricting coagulation to the site of injury or for dampening coagulation uses inhibitors that circulate in blood at high concentrations, sopping up the activated clotting enzymes. Once a complex between enzyme and inhibitor is formed, it is rapidly removed from circulation and degraded. Tissue factor pathway inhibitor (TFPI) is one regulator of hemostasis. Following the generation of sufficiently high levels of factor Xa by factor VIIa (Fig. 1), TFPI generates a complex, TFPI-factor Xa-tissue factor-factor VIIa, that inhibits factor VIIa function. Thus, this inhibitory mechanism dampens the coagulation cascade. Another important inhibitor, antithrombin, inhibits thrombin and factor Xa (Fig. 1). This protein belongs to a class of inhibitors called *serpins*, and operates by an interesting mechanism analogous to a mousetrap. In contrast to proteins like factor VIII and factor V, which thrombin binds, cleaves and releases, antithrombin is bound and cleaved by thrombin, but then traps thrombin in a complex. Heparin increases antithrombin inhibition 1000-fold (Fig. 1), which has led to its use as a therapeutic anticoagulant. A structure similar to heparin resides on the surface of endothelial cells, providing a defense mechanism for inhibiting activated proteases that escape from the site of injury.

One feature of coagulation that is critical for its effectiveness is the exquisite specificity of the clotting factors. Many of the clotting proteases evolved from a common ancestral protease related to the enzyme chymotrypsin. Chymotrypsin is a promiscuous protease that cleaves almost any protein. In contrast, each clotting factor cleaves only a few specific proteins. For example, factor Xa is the only enzyme that can cleave

prothrombin to activate it to thrombin (Fig. 1). Another component of the specificity of coagulation is the manner by which the proteins recognize each other to carry out a specific reaction. For example, factor IXa recognizes factor VIIIa but not factor Va as a cofactor and binds and cleaves factor X but not prothrombin. The ability of each protease to recognize its cofactor and to cleave a specific protein is dependent upon its structure, which differs for every protein.

Protein Structure

Factor IX will be used as an example of how an individual protein's structure imparts the specific function for that protein in hemostasis. As described, factor IX and chymotrypsin most likely evolved from a common ancestor, and half of factor IX is similar in structure to chymotrypsin. However, during evolution the factor IX molecule has acquired additional functions. These parts of the molecule allow factor IX: (1) to be secreted into the bloodstream after its synthesis; (2) to be targeted to the cell surface during coagulation; (3) to be activated by factor XIa cleavage; and (4) to interact with a specific cofactor (factor VIIIa). The unique amino acid sequence, or structure, of factor IX is what enables this molecule to carry out its specific functions. This factor IX structure is similar to three other proteins involved in hemostasis: protein C, factor X and factor VII. However, the differences between each protein which make their structures unique allow them each to perform their own specialized function. The ability to determine a protein's structure, as well as its function, has been profoundly affected by the development of recombinant deoxyribonucleic acid (DNA) technology. Prior to the availability of this technology, only a small number of proteins existed in amounts sufficiently abundant to make structural determination possible. In contrast, now it is possible to isolate the DNA encoding an individual protein and sequence the DNA to determine the predicted amino acid sequence of the protein. Another powerful component of recombinant DNA technology is the ability to change individual amino acids and then measure the effect of the change on function. Such manipulations have been instrumental in determining which parts of a protein are important for specific functions.

From the factor IX DNA sequence, factor IX is known to comprise 415 amino acids, representing the protein form that circulates in blood (Fig. 3). Factor IX is composed of different structural "domains," where each domain has a distinctive function. For example, the catalytic domain (Fig. 3) is the region of factor IX that evolved from the primitive chymotrypsin-like protease. This domain has three key amino acids (labeled S, D and H in Fig. 3) which are common to all proteases in the chymotrypsin family and which these enzymes require for activity. The growth factor domain is important for protein-protein interaction and plays a role in the specific recognition of factor VIII by factor IX. This domain binds calcium, a metal which is important to hemostasis. Most of the clotting factors bind calcium (in the growth factor domain or elsewhere) and most of the reactions in the clotting cascade (Fig. 1) depend upon this metal for activity. In some cases, calcium is required to stabilize the structure of the molecule (e.g. in the growth factor domain). In other cases, calcium is required for the protein to bind to the cell surface (as described in the next section).

Two regions of factor IX are important for processing to give a mature, active enzyme. One region encompasses 46 amino acids important in the secretion and modification of factor IX (Fig. 3). This region is cleaved at two sites: the first cleavage removes a signal peptide which is responsible for targeting the factor IX for secretion and the second cleavage removes a propeptide which is responsible for signaling the cell to modify factor IX (as described below). The other region where processing occurs involves the activation of factor IX by factor XIa cleavage at two different sites results in the release of a small peptide and the activation of factor IX to factor IXa. This activation reaction has been exploited in an interesting example of natural mimicry. Vipers possess an enzyme in their venom that performs the same reaction as factor XIa, which these predators use to induce clotting to overcome their prey. Many other adaptive mechanisms preventing or promoting coagulation have been found in bats, leeches and snakes. Characterization of these agents has provided useful information and tools for defining the process of hemostasis.

Proteins are synthesized from a set of 20 common amino acids that can be further modified to affect protein function. Factor IX is an example of a protein with extensive modifications. These changes include two

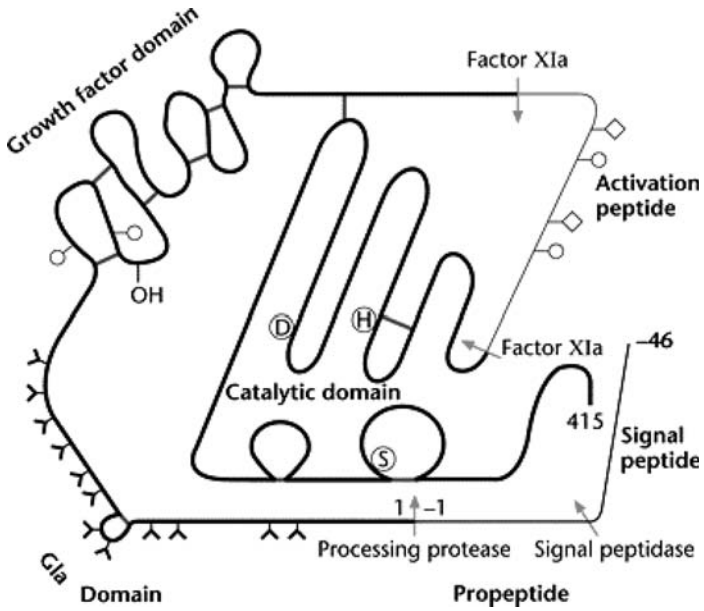

Fig. 3. Structure of factor IX. Factor IX that circulates in blood has 415 amino acids and the intracellular form (most of the clotting factors are synthesized in liver) has an additional 46 amino acids (indicated as -46 to -1). During secretion, these 46 amino acids are removed by two different proteases, as indicated by the arrows. Factor IX is processed further by factor XIa, which cleaves at the two sites indicated by the arrows to release an activation peptide and to generate activated factor IX (factor IXa). The shaded bars show several bonds, called disulfide bonds, which help stabilize the three-dimensional structure of factor IX. As described in the text, three different kinds of amino acid modifications occur in factor IX: the addition of carbohydrates at six locations (indicated by circles and diamonds), the addition of a hydroxyl group to one amino acid (in the growth factor domain) and carboxylation of 12 amino acids (indicated by the 'Y's in the Gla domain). The three circled letters represent key residues required for factor IXa activity.

different types of carbohydrates added at six different locations (Fig. 3), which probably stabilize factor IX as it circulates in the blood. Another amino acid, in the growth factor domain, undergoes a reaction that adds a hydroxyl group. The full functional significance of this modification is not yet known. The last modification is the carboxylation (addition of carboxyl groups) of 12 glutamic acids. The modified amino acids are called Gla residues, and so this region of factor IX is referred to as the Gla domain (Fig. 3). Carboxylation is required for factor IX activity, and occurs with several proteins involved in hemostasis.

Role of Vitamin K

Factor IX belongs to a class of proteins called *vitamin K-dependent proteins*. Vitamin K is used in a reaction that generates the Gla residues in the vitamin K-dependent proteins required for their activity. A connection between vitamin K and coagulation (K stands for the German word *Koagulation*) was first made in the 1920s: chicks fed a lipid-free diet hemorrhaged, and identification of the missing factor led to the discovery of a new vitamin, vitamin K. How vitamin K affected hemostasis was not established until decades later, when it was shown that several of the hemostatic proteins are vitamin K-dependent proteins. These proteins (factor VII, factor X, protein C, protein S, prothrombin and factor IX) all have a similar Gla domain and propeptide (Fig. 3). During secretion, the propeptide acts as a signal to traffic these proteins to an enzyme in the endoplasmic reticulum, the ã carboxylase. This enzyme then generates the Gla residues, using vitamin K. These Gla residues coordinate several molecules of calcium, causing a structural change in the Gla domain. This change allows the Gla domain to bind to the membranes that make up the cell surface (Fig. 2), orientating the enzyme so that it is now positioned to interact effectively with other proteins (e.g. factor VIIa with tissue factor).

Because many of the hemostatic proteins are vitamin K-dependent proteins, antagonizing their function has been exploited to inhibit blood clotting when necessary, for example during surgery. Both natural antagonists (coumarins) and synthetic antagonists, for example warfarin, have been used to inhibit coagulation. These anticoagulants have been useful for a

number of clinical indications, such as in deep vein thrombosis: following surgery there are frequently complications due to clot formation at sites distal from the original wound. This situation is an example where the body does not have the capacity to restrict adequately coagulation to the site of injury (Fig. 2). However, inhibiting coagulation with warfarin (given in conjunction with heparin) has been found effective in reducing deep vein thrombosis. The dosage is critical: the body still requires the capacity to effect some clotting and so therapy balances the prevention of thrombosis against bleeding risks. Many different parameters can alter the effectiveness of warfarin. One example is diet. An important source of vitamin K is ingestion, so consumption of sources rich in vitamin K (e.g. green, leafy vegetables) opposes the action of warfarin. Numerous drugs can also affect anticoagulant therapy; for example, barbiturates, which cause warfarin degradation. Another more complex example is aspirin, which indirectly affects warfarin therapy because aspirin inhibits platelet deposition in the hemostatic plug (Fig. 2). Aspirin thus potentiates the anticoagulant effect of warfarin. Because so many different variables have the potential to affect some aspect of hemostasis, they need to be factored in during anticoagulant therapy. Consequently, monitoring the ability of a patient to clot is a critical component of therapy. See also **Anticoagulants**; and **Deep Vein Thrombosis and Pulmonary Embolism**.

A comprehensive understanding of the process of hemostasis will clearly provide the best rationale for anticoagulant therapy. The hemostatic process is a complex one (Figs. 1 and 2) that is not yet fully understood, and there is an intense effort to define the overall mechanism. An excellent example of how acquiring such knowledge should ultimately lead to the best therapy is the fact that, while the first vitamin K-dependent proteins discovered were those in hemostasis, others have now been identified that have functions unrelated to hemostasis. These proteins were not known to exist when anticoagulant therapies based on inhibiting vitamin K-dependent proteins were implemented. Thus, the anticoagulant therapies affect other biological processes, such as bone morphogenesis, which need to be evaluated in order to develop the best overall therapeutic strategies.

Hemophilias

The hemophilias are bleeding disorders that result in a defect in individual (or, in rare cases, multiple) proteins required for normal hemostasis. These defects can arise by several different genetic alterations. The most common mutations are those which cause single amino acid changes in proteins. Such changes impart consequences ranging from severe to no effect, depending upon where the amino acid is located in the protein and what kind of amino acid change occurs. For example, a mutation in factor IX that changes one of the three key amino acids in the catalytic domain (Fig. 3) would result in an inactive enzyme and severe hemophilia. Mutations can also result in truncated proteins, which are almost always nonfunctional. Another class of mutations results in altered levels of a protein. This class of mutations occurs in the noncoding parts of the gene, which can affect regulation of gene expression and result in decreased levels of what would otherwise be a functional protein. The consequences of these different mutations are defects in hemostatic function that show up clinically as bleeding disorders. See also **Hemophilia**.

The most common hemophilias are hemophilia A and hemophilia B, which result from defective factor VIII or factor IX genes, respectively. These hemophilias are the most frequent ($\sim$1/8000 for factor VIII and $\sim$1/30 000 for factor IX) because the genes encoding factor VIII and factor IX are X-linked.

Summary

The hemostatic process is not yet fully understood. This article has focused on the hemostatic response to injury; however, physiological changes can also affect hemostasis even in the noninjured. For example, viral infection or inflammation can result in the expression of tissue factor on the endothelium, turning this once protective barrier into a procoagulant surface. Our understanding of hemostasis has been greatly accelerated by several advances, for example the recombinant DNA technology described above. Another important advancement has been the ability to generate knockout mice, in which individual genes are deleted and the effect of this loss is measured to assess the function of the protein. This technology has been a powerful tool for distinguishing the *in vivo* roles of the various coagulation factors. For example, the observation that tissue factor- and factor VII-knockout mice show different lethalities (tissue factor deficiency leads to death at the embryonic stage while factor VII deficiency causes death shortly after birth) has indicated an additional function for tissue factor in embryogenesis which is independent of coagulation. Other significant new information includes the recent determinations of X-ray crystallographic structures of clotting factors, which provide a three-dimensional picture to show how the proteins function. Finally, advances in the area of cell biology have revealed an entirely new level of complexity that links coagulation to other processes: several of the proteases that participate in hemostasis (factor VII, protein C, factor X and thrombin) have also been shown to act as hormones, targeting specific receptors to trigger intracellular signal transduction pathways that affect other biological systems like cell proliferation, migration and adhesion. Our current view of hemostasis is thus likely simplistic, and these areas of investigation should provide exciting and important new information that will allow us to more fully understand the complex process of hemostasis.

BLOOD COAGULATION. The blood coagulation system acts in concert with the platelets to seal damaged blood vessels by the formation of a clot that consists of aggregated platelets interwoven with fibrin. Coagulation is initiated by the subendothelial membrane protein tissue factor and proceeds through a highly regulated proteolytic cascade to the production of thrombin and the fibrin clot.

In higher animals, blood is pumped through the vascular system under pressure. It is the job of the hemostatic system to maintain this system. Upon injury to the endothelium, which lines all blood vessels, the two component systems of hemostasis are initiated together. One is the activation and subsequent aggregation of the blood platelets to form a platelet "plug," which is initiated by the interaction of platelets with materials — chiefly collagen — present in the vessel wall behind the endothelium. The other is the coagulation system, which is initiated by a specific membrane protein of cells in the vessel wall, again behind the endothelium, called tissue factor (TF). The products of coagulation are the enzyme thrombin and the insoluble gelatinous protein of the final clot, called fibrin. Platelet function and coagulation are often separated for didactic reasons, but the two systems are closely intertwined, each requiring the other for its function; and a normal clot consists of an interlocked structure of aggregated platelets and fibrin. In its general form, the collection of plasma clotting proteins and platelets can be viewed as a primed system, set to generate a rapid and highly amplified response to a TF stimulus. See also **Blood Clotting: General Pathway** and **Platelets**.

The initiating reaction of coagulation is the formation of a complex between TF and a plasma zymogen, factor VII. This starts a cascade of

reactions that produce a series of highly specific proteolytic enzymes, or proteases. Like other complex proteolytic systems, coagulation is subject to numerous intermeshed controls, including regulation by cofactor proteins of plasma and the vessel wall, positive and negative feedback controls, and the action of protease inhibitors. The result is a system that, in concert with platelets, can seal areas of endothelial damage very quickly, and moreover restrict this response to the area of damage even in the face of flow. The vast majority of clinical defects in hemostasis cause thrombosis rather than bleeding, and most of these are due to pathological changes in the blood vessel wall, particularly in areas of the arterial vasculature where sclerotic plaque formation is common, such as the coronary and carotid arteries. Apart from the fact that plaques narrow the arteries, they also contain very high levels of TF, and its release upon rupture is the dominant cause of thrombus formation in acute arterial thrombosis. Much is known of risk factors for the development of arteriosclerosis, which include the importance of lipid metabolism and methionine metabolism. See also **Lipids** and **Proteases**.

Although arterial thrombosis is more common, venous thrombosis is of major clinical importance. With the discovery of factor V Leiden and common polymorphisms that lead to increased prothrombin and factor VII synthesis, the evidence is increasingly strong that most venous thrombosis is caused by defects in the plasma proteins of the clotting system rather than defects in blood vessels. These may be either quantitative (e.g., abnormal plasma levels of inhibitors or clotting factors) or qualitative (e.g. the genetic defect in factor V Leiden that increases the risk of thrombosis).

Zymogens, Proteases, Cofactors, Inhibitors

Table 1 lists the major proteins involved in blood coagulation and its control.

A zymogen is the precursor of an enzyme: conversion to the enzyme involves proteolytic cleavage of the zymogen protein chain by a protease at just one or two sites (peptide bonds). Conversion of a zymogen to an enzyme is also called *activation*. (Zymogen activation by specific, regulated, proteolytic cleavage is by no means restricted to coagulation: many complex systems have this as a central activation mechanism; examples include complement, fibrinolysis, blood pressure regulation and apoptosis.) All but one of the clotting zymogens are precursors of proteases, the exception being factor XIII, which is the precursor of a transglutaminase that catalyses the crosslinking of fibrin polymers and the linking of fibrin to cell matrix proteins like fibronectin. See also **Proteases**.

Proteases produced by the activation of the other zymogens (XII, XI, X, IX, VII and prothrombin) are all of the trypsin-like family, i.e. they are serine proteases that preferentially cleave at basic amino acid residues. However, all are much more specific than trypsin: they cleave their substrates only at arginyl (never lysyl) bonds, and even then they cleave only one or two of the many arginyl bonds in their target molecules. Clotting proteases are denoted by adding "a" to the Roman-numeral factor name; for example, activation of the zymogen factor X produces the active protease factor Xa. In contrast to the family characteristics of the clotting zymogens, the cofactors are a diverse group. A cofactor is a protein that has no catalytic site, but regulates the activity of an accompanying protease. TF is a cofactor that binds factor VII in the initiating event of clotting, and is required for the proteolytic activity of the formed protease factor VIIa. Another critical regulatory membrane protein cofactor is thrombomodulin, which resides on the vascular surface of endothelial cells. It functions as a special cofactor to thrombin, diminishing the enzyme's procoagulant action on fibrinogen or platelets, and greatly augmenting its activity on protein C, which initiates an anticoagulant pathway. The other two cofactors, factors VIII and V, are found in the plasma and platelets, and they play central regulatory roles in controlling the activity of their respective proteases (factors IXa and Xa). They are closely related, very large molecules, and are synthesized as inactive, or almost inactive, precursors. They are converted into the active cofactors (VIIIa and Va) by the proteolytic action of thrombin. See also **Anticoagulants**; **Blood**; and **Protein**.

Although a number of protease inhibitors of the plasma can inhibit clotting enzymes, just two are known to be important in regulating coagulation. Antithrombin III (ATIII) is a member of the serpin class of inhibitors, and its chief target enzymes are thrombin and factor Xa. TFPI is also a major regulator, and homozygous expression of a defective inhibitor in mice is lethal to the embryo [Huang, et al.:]. TFPI is not an ordinary serpin, and has separate inhibitory domains for two clotting enzymes: factor Xa and the TF–VIIa complex [Girard, et al.:].

Synthesis of Plasma Clotting Proteins. The liver is the major site of synthesis for probably all the plasma clotting proteins, although some are known to be synthesized to some extent in other tissues particularly prothrombin, and possibly factor VIII. Factor VIII is also complicated in its being transported in the blood bound to von Willebrand factor. This protein is synthesized mainly in the endothelial cells, and it too has a central function in hemostasis, playing a major role in the initial adhesion of platelets to proteins of the damaged vessel wall. The platelet α granules also contain varying amounts of some plasma coagulation proteins — factors XI, VIII, V, fibrinogen and TFPI — but it should not

TABLE 1. NAMES, FUNCTIONS AND LOCATIONS OF BLOOD COAGULATION PROTEINS

Common name	Common alternative name	Infrequent or archaic name	Function (location)
Tissue factor	Thromboplastin	CD142, factor III	Cofactor, initiator (subendothelium)
Factor XII	Hageman factor		Protease zymogen (plasma)
Factor XI		Plasma thromboplastin antecedent (PTA)	Protease zymogen (plasma)
Factor X[a]		Stuart factor	Protease zymogen (plasma)
Factor IX[a]		Christmas factor	Protease zymogen (plasma)
Factor VIII	Antihaemophilic factor		Cofactor for factor IXa in factor X activation (plasma)
Factor VII[a]		Proaccelerin	Protease zymogen (plasma)
Factor V		Labile factor	Cofactor for factor Xa in prothrombin activation (platelets, plasma)
Prothrombin[a]	Factor II		Protease zymogen (plasma)
Fibrinogen		Factor I	Fibrin precursor (plasma)
Factor XIII		Fibrin-stabilizing factor	Zymogen of transglutaminase (platelets, plasma)
Thrombomodulin			Cofactor for thrombin in protein C activation (endothelial surface)
Protein C[a]			Protease zymogen (plasma)
Protein S[a]			Cofactor for activated protein C (plasma)
Antithrombin III	Antithrombin	Heparin cofactor	Protease inhibitor (plasma)
Tissue factor pathway inhibitor (TFPI)		Extrinsic pathway inhibitor (EPI); lipoprotein-associated coagulation inhibitor (LACI)	Protease inhibitor (platelets, plasma, endothelial surface)

[a] Vitamin K-dependent proteins.

be concluded that these are synthesized in the megakaryocyte (the platelet precursor cell in the bone marrow). In the case of factor V and fibrinogen, the plasma protein pool is the source, and this may be true of others too. The relative importance of the platelet-derived proteins in hemostasis is difficult to assess. Platelet factor V has been clearly shown to be of central importance, and more significant than the plasma pool of this protein. The same is likely true of TFPI, which exists in the plasma at a minuscule concentration (see **Inhibitors**). The plasma levels of the clotting proteins remain essentially constant, with no evidence for significant inductive or repressive control of expression levels.

The Cascade

Initiation. TF is the physiological initiator of blood coagulation. However, an alternative pathway of initiation occurs *in vitro* that involves factor XII and its interaction with negatively charged often nonphysiological, surfaces. Examples are glass and other silicates, ellagic acid, sulfated lipids and sulfated polysaccharides. (It is this pathway that causes blood to clot in contact with glass.) Regardless of whether or not such initiation occurs *in vivo*, the key observation is that people who lack factor XII are clinically normal, even to the extent of being able to undergo major surgery. Thus, if this pathway, sometimes called the intrinsic pathway, does normally function, its contribution to hemostasis is small. In contrast, a deficiency of TF has never been observed in humans, and is probably lethal. In studies of transgenic mice, more than 80% of $TF^{-/-}$ mouse embryos die from hemorrhage into the yolk sac around day 10 of embryogenesis, at the time the vascular system begins to form [Bugge et al.; and Toomey, et al.:].

Figure 1 shows the major features of initiation. The initiating complex (crystal structure: Banner, et al.:) is formed when the blood protein factor VII comes into contact with TF (TF–VII). Although this is a zymogen complex and has no measurable protease activity, there is always a trace of factor VIIa (less than 1% of the factor VII level) in plasma [Morrissey, et al.:]. This enables a trace of TF–VIIa to be formed upon the appearance of TF, sufficient to activate a little factor X and enable the feedback loop of factor Xa generation and TF–VII activation. This direct activation of factor X, however, is *not* the route of *bulk* factor X activation. *In vivo*, most factor Xa is generated by the parallel route involving factors IX and VIIIa. From the severe bleeding seen in hemophilia A and B, which arise from deficiencies of factors VIII and IX, it is clear that these factors are critical to normal hemostasis. Although not experimentally proven, there are two likely reasons that this pathway generates more factor Xa than does the direct pathway. (1) TF–VIIa is rapidly shut down in a negative feedback by TFPI, and direct factor X activation must then cease (see below); and (2) once factor IXa is formed, it is relatively stable, and the extra step that it catalyses provides substantial extra amplification. See also **Hemophilia**.

Sources of TF. TF is not expressed at significant levels in quiescent endothelial cells or blood cells; thus, cellular TF is not normally in contact with the blood. Endothelial cells form a continuous layer, one cell thick, which lines the entire vascular system, amounting in adults to some 700 m^2. Much richer in TF are the fibroblasts and smooth muscle cells of the vessel wall, behind the endothelium, and these two cell types are probably the major source of vascular TF, which is the major initiator when the endothelium is physically damaged. However, blood also contains circulating TF in two forms. Monocytes and macrophages can express significant levels of TF in response to a variety of stimuli that are seen in inflammation, infection and atherosclerosis. Additionally, however, blood contains a constant low level of noncellular TF, most of it in the form of small vesicles that are apparently derived from these cells.

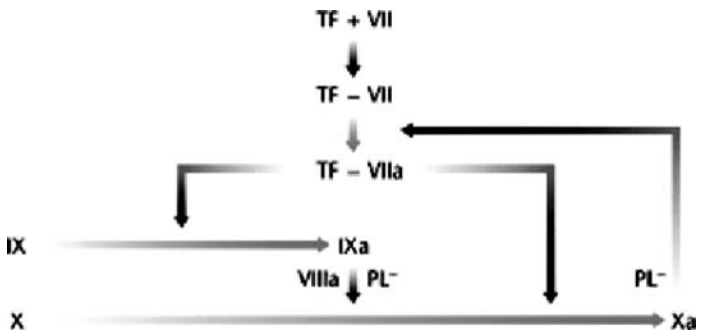

Fig. 1. The initiation of clotting by tissue factor (TF): parallel pathways to factor Xa formation, and the feedback role of factor Xa in TF–VIIa generation. Blue arrows denote the action of an enzyme (e.g., TF–VIIa, IXa) in catalyzing the reaction pointed to; green arrows indicate the proteolytic reaction being catalyzed. Species shown beside an arrow (here, VIIIa and anionic phospholipid, PL^-) denote required cofactors.

Although its role in *initiation* is unclear, circulating TF may play a major role in the *propagation* of the clot. If subendothelial cell-bound TF were the sole TF source for initiation, factors IXa and Xa generation would be restricted to TF-bearing cells, and the growth of the clot would be dependent on the diffusion of these enzymes from the site of their generation into the growing platelet plug. Given the speed of clot growth, and the fact that diffusion of both enzymes is restricted — not only because proteins diffuse very slowly in solution but also because they bind tightly to the anionic phospholipid of activated platelets — rapid thrombin and fibrin formation requires that factors IXa and Xa generation must also occur within the clot. And indeed it has recently been shown that clots that form in the presence of whole blood do contain substantial levels of TF [Balasubramanian, et al.:]. The source of this is circulating TF, which is available to, and binds to, activated platelets during clot formation, both *in vitro* and in animal models *in vivo*, with P-selectin on the surface of the activated platelet having a major role [Falati, et al.:].

Although circulating TF can explain how clots are propagated so rapidly, its existence also raises the question of how the system maintains a quiescent state even in the face of a continual low-level stimulus. This is not yet definitively answered, but we propose that the requirement for positive feedbacks is closely involved (see **Positive Feedbacks**).

Thrombin. Once formed, factor Xa goes on to activate prothrombin, generating the enzyme thrombin. Just as factor IXa requires activated factor VIII (VIIIa) as a cofactor in the activation of factor X, factor Xa requires a cofactor in prothrombin activation — in this case, factor Va. Both reactions also require anionic phospholipid. Factors VIII and V are closely related in both structure and function, and both are subject to essential regulatory feedback control (both positive and negative) by thrombin. In the normal physiological setting, prothrombin activation occurs on activated platelets, which provide both anionic phospholipid and factor Va (Fig. 2) (see also **Localization**).

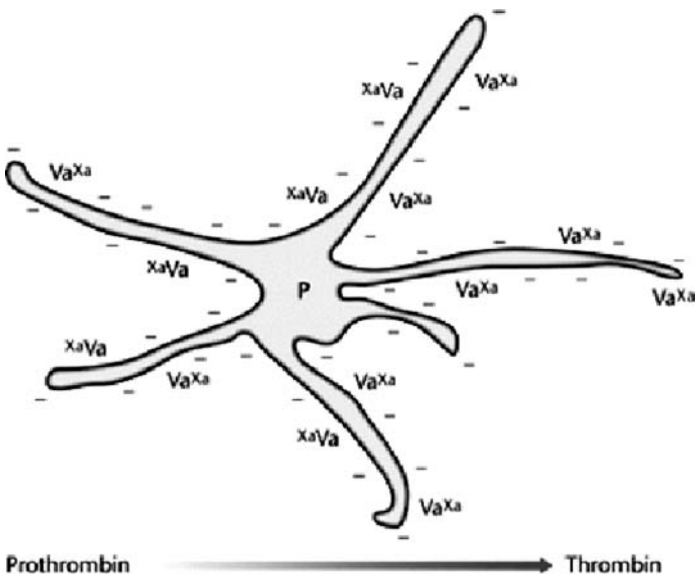

Fig. 2. Prothrombin activation. Activated platelets (P) provide the necessary cofactors, anionic phospholipid (–) and factor Va, required for maximum efficiency of the proteolytic action of factor Xa on prothrombin.

Functions of Thrombin. Thrombin is the final protease produced in clotting and has diverse roles, some of which have been mentioned:

1. It forms fibrin by removing small peptides proteolytically from the Aα and B peptide chains of fibrinogen.
2. It is the major feedback activator of plasma factors VIII and V, converting the inactive, or near-inactive, plasma species of these proteins to the active cofactors that regulate their respective proteases.

(Platelet factor V, however, is activated intracellularly concomitant with its release from the α granules upon platelet activation.)

3. It is a major agonist, or activator, of platelets and thus plays a central role in linking the platelet and clotting systems in hemostasis.
4. In concert with the endothelial protein thrombomodulin, it initiates the anticoagulant protein C pathway (see Negative Feedback Controls).
5. Many reports exist of thrombin affecting fibrinolysis function, both positively and negatively, and the overall balance in the physiological picture is confused. Examples include a thrombin-activatable fibrinolysis inhibitor (actually a thrombin-activated peptidase: Nesheim, et al.:) and the thrombin-inducible expression in endothelial cells of tissue plasminogen activator [Emeis, et al.:], urokinase Shatos, et al.:) and plasminogen activator inhibitors [Wojta, et al.:].
6. Thrombin also catalyses another significant feedback, activating factors XI to XIa in the presence of activated platelets [Baglia and Walsh]. Years ago, it was thought that factor XI was activated during normal clotting by factor XIIa (see Initiation). However, whereas factor XII has no apparent function in hemostasis, factor XI does: most people deficient in this protein usually bleed to some extent, although the clinical picture is less severe than in hemophilia A and B.

Fibrin. Thrombin converts the soluble plasma protein fibrinogen to a molecule that spontaneously polymerizes to form fibrin gel, shown diagrammatically in Fig. 3. Fibrinogen is a dimer of a trimer, containing two Aα chains, two B chains and two γ chains, with the amino (*N*)-termini of all six disulfides linked in a central domain. Thrombin ("IIa" in Fig. 3) proteolytically cleaves small peptides (fibrinopeptides A and B) from the *N*-termini of the Aα and B chains, forming the fibrin monomer unit. Polymerization involves noncovalent, mainly ionic, interactions between the central domain of the molecule and the larger terminal domains of two neighboring molecules, forming an initial two-strand polymer with a half-staggered overlap (Fig. 3). Initially quite weak, fibrin polymer is later crosslinked by the action of factor XIIIa to form a stronger and more stable structure. Crosslinking also makes fibrin more resistant to the fibrinolytic enzyme plasmin. Factor XIIIa is itself formed from a zymogen by the action of thrombin.

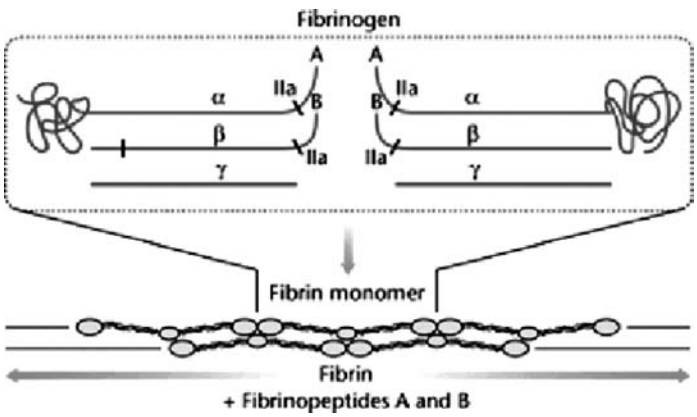

Fig. 3. Fibrin formation and initial polymerization. Thrombin (IIa) cleaves fibrinopeptides from the central *N*-termini of the Aα and B chains of fibrinogen. The "fibrin monomer" formed polymerizes to form an initial half-staggered two-chain protofibril of fibrin.

Localization. The most important regulatory feature of the clotting system is that clot formation is confined to sites of blood vessel damage. Only in pathological states is systemic activation and fibrin formation seen. This is called *disseminated intravascular coagulation* (DIC), and is often caused by the systemic release of large amounts of TF into the circulation, by a wide variety of mechanisms that include major organ injury.

Activated Platelets. The chief agent in localization is the activated platelet. Remember that platelet adhesion and activation are initiated by components of the subendothelium at the same time as the clotting system is initiated by TF. Platelets adhere to several proteins of the damaged vessel wall, where they are activated concomitantly, and then adhere to and activate one another to produce platelet aggregates. As far as clotting is concerned, the key event in platelet activation is the translocation of anionic phospholipid from the inner leaflet of the platelet cell membrane to the outside. In contrast, quiescent platelets — and indeed all other quiescent cells — actively restrict aminophospholipids, including the key anionic phospholipid, phosphatidylserine (PS), to the inner leaflet of their cell membranes by means of an adenosine triphosphate-dependent aminophospholipid translocase [Bevers, et al.:], but this polarized distribution is lost upon cell activation and PS appears on the outside. PS of the activated cell surface binds Ca^{2+} (present in the plasma), and this enables the binding of the vitamin K-dependent proteins of clotting. See also **Platelets**.

Vitamin K-dependent Factors, Coumarin Anticoagulants. Six coagulation proteins require vitamin K for an essential posttranslational modification that is closely related to their binding to PS: factors VII, IX, X and prothrombin in the cascade leading to thrombin generation, and proteins C and S in the anticoagulant protein C pathway. The endoplasmic reticulum of hepatocytes contains a vitamin K-dependent carboxylase, which modifies all the glutamic acid residues in the immediate *N*-terminal domains of these proteins, up to about amino acid residue 50. Depending on the protein, there are 9–12 modified glutamic acids in this domain, and they tend to come in pairs. All subsequent glutamic acid residues remain unmodified through to the Carboxy (*C*)-terminus.

The product of carboxylation is γ-carboxyglutamic acid, denoted by the abbreviation Gla. The Gla domains bind Ca^{2+}, which probably serves as a bridge to anionic phospholipids (Fig. 4). As normal cells do not have significant amounts of PS on their outer surfaces, in the vasculature this binding should be restricted almost exclusively to activated platelets. (Other mechanisms are probably involved in the binding of Gla domains to phospholipid, and several of these proteins contain other Ca^{2+}-binding sites, but these are not within the scope of this article.)

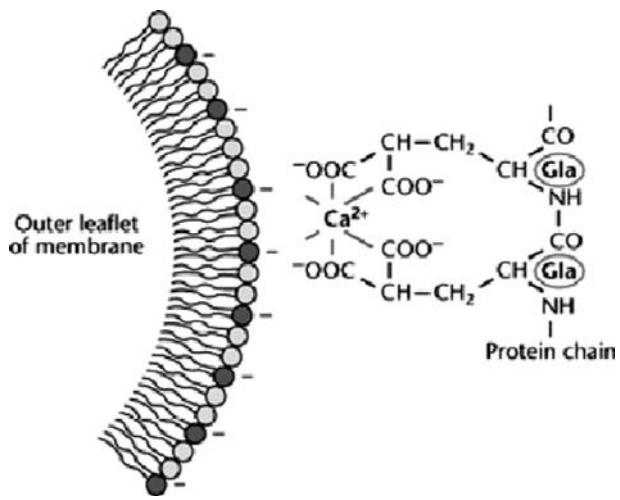

Fig. 4. Role of γ-carboxyglutamic acid (Gla) in the Ca^{2+}-dependent binding of vitamin K-dependent factors to anionic phospholipid. Anionic headgroups (e.g. phosphatidylserine) are shown as red circles (–), and neutral headgroups (e.g. phosphatidylcholine) as pink. The protein's peptide chain, on the right, has a pair of Gla residues in sequence.

Vitamin K is a fat-soluble quinone produced by the gut bacteria and by many green vegetables. The daily requirement is extremely low and deficiency is rare. However, antagonists to vitamin K — the coumarins or coumadins — are used frequently for long-term anticoagulant therapy after thrombotic episodes such as deep-vein thrombosis, pulmonary embolism, strokes and heart attacks. They include Warfarin and Dicoumarol. In addition to therapeutic use, they are commonly used as mouse and rat poisons. See also **Anticoagulants**.

Positive Feedback Controls

The clotting system includes many positive feedbacks, in which an enzyme formed later in the cascade (factor Xa or thrombin) feeds back and activates an earlier zymogen or cofactor precursor (Fig. 5). Some are of doubtful importance, but these are major: (1) factor Xa activates the TF–VII zymogen complex to TF–VIIa; (2, 3) thrombin activates the

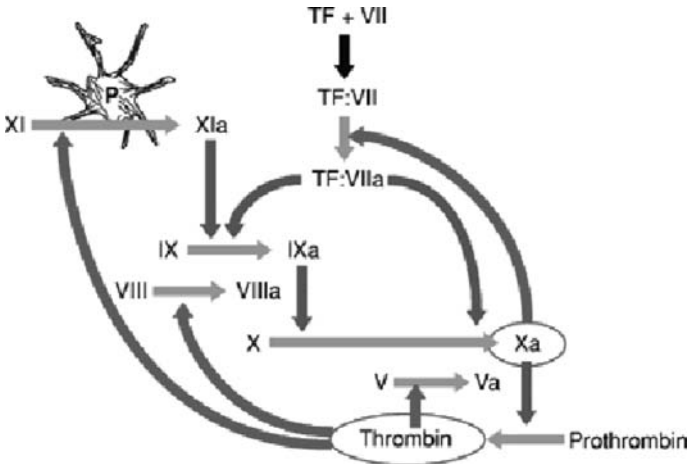

Fig. 5. Positive feedback controls (red arrows). (1) Activation of TF–VII by factor Xa is essential in initiating the system. (2,3) Thrombin activates the required cofactors, factors V and VIII. (4) Thrombin, in the presence of activated platelets (P), also activates factor XI to generate factor XIa, thereby bypassing contact activation (see Initiation). Blue and green arrows are as in Figure 1.

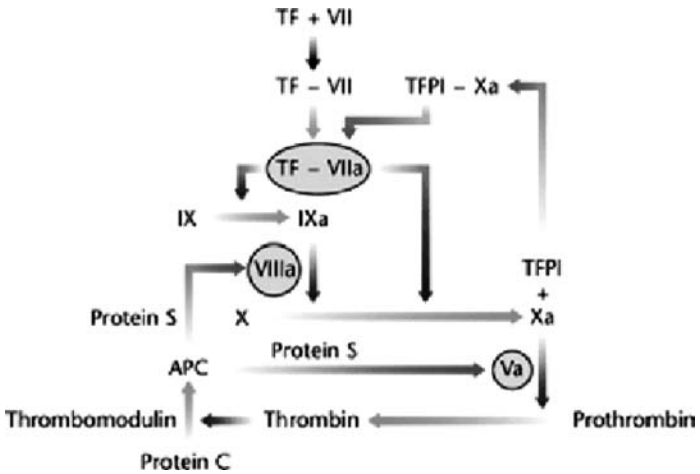

Fig. 6. Negative feedback controls (red arrows). (1) Inhibition of tissue factor (TF)–VIIa by tissue factor pathway inhibitor (TFPI) first requires reaction with factor Xa, the TFPI–Xa complex formed being the inhibitor of TF–VIIa. (2) The protein C pathway, initiated by thrombin in the presence of thrombomodulin, entails the proteolytic inactivation of factors VIIIa and Va by activated protein C (APC). Protein S plays a cofactor role. Blue and green arrows are as in Figure 1.

cofactor precursors VIII and V to their active states; (4) thrombin activates factor XI in the presence of activated platelets (**Thrombin**, above); and (5) thrombin activates platelets, providing anionic phospholipid and platelet factor Va (Fig. 2). There is no immediately obvious reason for the existence of several positive feedback mechanisms. Why, for instance, are factors VIII, VII and V not synthesized as the already-active molecules, ready to perform their function immediately upon activation of the system? Beltrami and Jesty [1995] have proposed that positive feedbacks, in concert with inhibition of the feedback enzymes, provide threshold behavior. In such systems, a threshold stimulus size should exist that depends on the balance of the kinetics of (i) the forward reactions, like thrombin generation, (ii) feedback reactions, like factor VIII activation, and (iii) enzyme inhibition, by ATIII. For a small enough stimulus, below the threshold, no significant feedback will occur and no clotting response will be generated, whereas above the threshold all feedbacks will be triggered and a fully amplified response will be generated. A critical part of this prediction is that if the kinetics of the forward reactions are inefficient, then the threshold stimulus will remain very high. This is of course the situation for the activations of factor X (by FIXa + FVIII) and prothrombin (by FXa + FV) in the absence of activated platelets. Although the theoretical behavior is clear from mathematical analysis, the proposal has not yet been testable experimentally. Nonetheless, it is probably central in ensuring that, as long as activated platelets are unavailable, the system is not triggered by low levels of circulating TF.

Negative Feedback Controls

Negative feedbacks are those where an enzyme is responsible for inactivating key component(s) necessary for its own formation. These are responsible for the inactivation — either inhibitory or enzymic — of three species generated during clotting: TF-VIIa, factor VIIIa and factor Va (Fig. 6).

Tissue Factor Pathway Inhibitor. TFPI is an unusual inhibitor with two sites that bind two enzymes, and it inhibits factor VIIa in the TF–VIIa complex by a two-step mechanism. The initial step is the combination of TFPI with factor Xa at one site. The resulting TFPI–Xa complex inhibits TF–VIIa by binding it at the other site. The requirement of TFPI for reaction with factor Xa means that TF–VIIa is present for a finite time before it is inactivated, thus allowing a pulse of TF–VIIa activity that decays rapidly once significant amounts of factor Xa are generated [Girard, et al.:]. During this period, factor IXa is also generated, enabling bulk factor X activation to continue after inactivation of the initiating TF–VIIa (see *Initiation*, above).

Protein C. The protein C pathway relies on the enzyme-catalyzed inactivation of cofactors. Thrombin forms a complex with thrombomodulin on the surface of the endothelium and thereby initiates a critical anticoagulant pathway [Esmon, ref.]. The thrombin–thrombomodulin complex activates protein C to an active protease (activated protein C, or APC), which along with its cofactor, protein S, inactivates the key regulatory cofactors, factors VIIIa and Va (Fig. 5). Like TFPI control, this mechanism ensures a pulse of thrombin formation over the period during which the cofactors are in their active state. The importance of the protein C pathway is clear from the systemic thrombosis seen in the rare newborns with homozygous protein C deficiency. A much more common, but less severe, genetic defect in this pathway exists in one of the target cofactors, factor V. Here, the factor Va generated, while having normal cofactor activity, is resistant to inactivation by APC and causes a significantly increased risk of thrombosis [Dahlback, ref.]. The mutation, called FV(R506Q) or factor V Leiden, is caused by a single base change in the factor V gene that changes Arg to Gln at one of the sites in factor Va that are cleaved by APC. It is essentially restricted to Caucasians, but in this group it is a major risk factor, the heterozygous state occurring in 5–15% of the population, and being found in 20–60% of cases of venous thrombosis.

Inhibitors

Antithrombin III. ATIII is a member of the serpin family of protease inhibitors and forms a 1:1 complex linked between a specific Arg residue of the inhibitor and the active-site Ser of the target protease. Although all the clotting proteases are inhibited at measurable rates by ATIII in the laboratory, the enzymes most rapidly inhibited (i.e. the major physiological targets) are thrombin and factor Xa. ATIII is present in the plasma at levels in large excess over its targets or their precursors, at a concentration of about 4 μmol L^{-1}. Even if the clotting zymogens were completely converted to enzymes — which never occurs, even in the most severe DIC — their total concentration would amount to only about one-third of the ATIII available. However, despite there being no scarcity of ATIII, heterozygous genetic defects that cause 40–60% reductions in ATIII concentration nonetheless greatly increase the risk of thrombosis. The reason is a kinetic one, the rates of inactivation of the target enzymes being proportional to the inhibitor concentration. It is likely that as well as affecting a "mopping up" function in inactivating enzymes generated during clotting, ATIII provides a permanent inhibitory capacity that regulates the proposed system threshold described under Positive Feedback Controls.

The incidence of heterozygous ATIII deficiency in the general population has been estimated at 0.02–0.05%. However, although overall this is much less than the incidence of factor V Leiden, the risk of thrombosis is greater. Approximately two-thirds of people with heterozygous ATIII deficiency will suffer a thrombosis during their lifetime, accounting for 2–5% of cases of venous thrombosis [Hirsh, et al.:].

Heparin. Heparin is a highly sulfated polysaccharide that is frequently used for anticoagulant therapy in the acute setting. Unlike coumarin therapy (see **Vitamin K**, above), heparin therapy is relatively easily controlled, and has the benefit that its anticoagulant effect is immediate.

Heparin is the anticoagulant of choice in the immediate treatment of thrombosis (heart attack, thromboembolic stroke, pulmonary embolism, etc.), and is also used for anticoagulation in surgical procedures that entail a significant risk of postoperative thrombosis. It works by greatly increasing the rate of inhibition of clotting proteases by ATIII, the extent of acceleration (and hence the degree of anticoagulation) being controlled by the heparin dose. Both natural and synthetic heparins exist. Ordinary heparin, isolated from pig-gut mucosa, is a mixture of peptidoglycans of varying sulfation and length, and of fairly high molecular weight (approximately 8–12 kDa). More specific heparin formulations are now available of low molecular weight (LMW), more specific properties and considerably higher cost. Most of these accelerate the inhibition of factor Xa by ATIII somewhat more than that of thrombin, but there is little evidence that this selective targeting of factor Xa is beneficial. More important are the other advantages of LMW heparins: they are routinely and effectively administered intramuscularly; they have increased bioavailability, at least in part because they are less subject to inactivation by antiheparin (chiefly platelet-derived) agents in the blood; they have substantially longer half-lives; and they are sufficiently predictable (particularly with regard to bioavailability) to be used without any monitoring of plasma levels.

BLOOD PRESSURE. The force exerted against the walls of the blood vessels by the circulating blood. Blood pressure within the arteries can be determined by using a device consisting of an elastic band around the arm, an air pump, and a column of mercury in a glass tube (manometer). The patient's age, his activity, the composition of blood, the secretion from the adrenal glands, and the thickness of the walls of the blood vessels all bear upon blood pressure.

Blood passing from the heart through the lungs has only about one-sixth of that pressure found when the blood is forced out over the body through the *aorta*. But, the pressure is sufficient to assure flow through the multitude of capillaries in the walls of the lungs. The lungs are composed of innumerable small sacs that have a supply of changing air. In the lung or pulmonary capillaries, the blood releases carbon dioxide and takes on oxygen.

The maximum pressure in the arteries is related to the contraction of the left ventricle of the heart, and is referred to as the *systolic pressure*. The minimum pressure, which exists just before the heartbeat that follows, is the *diastolic pressure*. The pressure of the blood in the smaller arterioles and in the capillaries is much less than in the arteries.

A number of factors must work together to maintain the blood pressure within normal limits. The pumping action of the heart itself is of major importance, as is the competency of the heart valves in closing so that no leakage occurs back from the arteries into the heart chambers. The elasticity of the arterial walls also influences the pressure. The resistance that the blood meets in the smaller blood vessels causes considerable variation. The amount of blood in the circulatory system and its viscosity also are factors. When any of these variables change markedly, the blood pressure may be increased or decreased. These pressure changes, in turn, may produce abnormalities in the structure and function of the heart and blood vessels. The most common variation in the blood pressure is an increase in its magnitude, which is referred to as hypertension, or high blood pressure. See also **Hypertension**; and **Heart and Circulatory System (Physiology)**.

BLOODSTONE. A massive variety of quartz of greenish color with small spots of red jasper somewhat resembling blood drops. It is used as a semiprecious stone. When placed in water in full sunlight bloodstone will frequently give a general reddish reflection, hence the term heliotrope, derived from the Greek words meaning sun and to turn. See also **Chalcedony**; and **Quartz**. Bloodstone also is known as *heliotrope*.

BLOOD WORM. 1. *Annelida*. Certain marine worms whose bright red blood gives color to the entire body. 2. *Insecta*, Diptera. The aquatic larvae of certain midges, which have hemoglobin dissolved in the plasma of the blood and so are red in color.

BLOOM. In surface-coating technology, bloom is a whitish, filmy layer that appears on films of paints, varnishes, or lacquers due to contamination from the atmosphere. The term is also applied to a filmy layer deposited on a photographic plate by tap water, which can be removed by rubbing the plate with wet cotton. The term bloom is used in metallurgy to denote a mass of malleable iron from which the slag has been removed. See also **Iron Metals, Alloys, and Steels**.

BLOWER. A type of machine used to compress air or other gases by centrifugal force to a final pressure between 1 and 35 pounds per square inch (7 and 245 kPa) gage. If the final pressure is below about 1 pound per square inch, the machine is known as a fan, while for pressures developed by centrifugal force above 35 pounds per square inch (2.4 atmospheres), the machine becomes a centrifugal compressor. Blowers driven at high rotative speeds (usually by steam or gas turbines) are usually called turboblowers.

BLOW-FLY *(Insecta, Diptera).* Flies that deposit their eggs on meat. The name is applied to an entire family, however, containing other species which breed in dung, in wounds on living animals, and as blood-sucking parasites of nestling birds. The commoner species are also known as bluebottle flies. Family: *Calliphoridae*.

The blow-fly has a black head and thorax with a steel-blue color abdomen. The eggs are long and cylindrical in shape and are deposited in stacks, many at a time. The larvae hatch in 24 hours and the insect is fully grown within 5 to 6 days. The blow-fly can spread disease by depositing infectious microorganisms on food.

BLOWHOLE. A nearly vertical hole, fissure, or natural chimney in coastal rocks, leading from the inner end of the roof of a sea cave to the ground surface above, through which incoming waves and the rising tide forcibly compress the air to rush upward or spray water to spout intermittently, often with a noise resembling a geyser outburst. It is probably formed by wave erosion concentrated along planes of weakness, as in a well-jointed rock. (*Glossary of Geology*, American Geological Institute.)

BLOWING DUST. Dust picked up locally from the surface of the earth and blown about in clouds or sheets. It is classed as a lithometeor and is encoded BLDU as an obstruction to vision in an aviation weather observation (METAR). (Encoded as BD in SAO observation format.) Blowing dust may completely obscure the sky; in its extreme form it is called a duststorm. A layer of stable air aloft tends to stop the vertical transport of dust by eddies. There is then a sharply defined upper limit to the dust layer.

AMS

BLOWING SAND. Sand particles picked up from the surface of the earth by the wind, reducing the horizontal visibility to less than 11 km (about 7 statute miles). This lithometeor is encoded BN as an obstruction to vision in a surface aviation weather observation and as BLSA as an obstruction to vision in a METAR or SPECI observation. In its extreme form, blowing sand constitutes a sandstorm.

AMS

BLOWING SNOW. Snow lifted from the surface of the earth by the wind to a height of 2 m (6 ft) or more above the surface (higher than drifting snow), and blown about in such quantities that horizontal visibility is reduced to less than 11 km (about 7 statute miles). As an obstruction to vision, it is encoded BS in a surface aviation weather observation and as BLSN as an obstruction to vision in a METAR or SPECI observation. Blowing snow can be falling snow or snow that already accumulated but is picked up and blown about by strong winds. It is one of the classic requirements for a blizzard.

AMS

BLOWING SPRAY. Water droplets displaced by the wind from a body of water, generally from the crests of waves, and carried up into the air in such quantities that they reduce the horizontal visibility to less than 11 km (about 7 statute miles). It is encoded as BY as an obstruction to vision in surface aviation weather observation and as BLPY as an obstruction to vision in a METAR (Meteorological Terminal Air Report) or SPECI observation.

AMS

BLOW MOLDING. See **Food Packaging**.

BLUEBIRD *(Aves, Passeriformes).* A term variously applied to different species of birds. In North America, the term usually signifies the eastern bluebird (*Sialia sialis*) or the western mountain bluebird (*Sialia currucoides*). The term is also applied to one of the babblers of the Orient, as well as to a South African albatross (order *Procellariformes*).

The eastern bluebird is found from Newfoundland southward to Florida and the Gulf of Mexico and westward to Manitoba and the midwestern United States, notably in the Ohio Valley Region. In New England, it is usually found in the coastal areas. It is not frequently found in the immediate vicinity of the Great Lakes. The bird is a bit larger than a sparrow. It is the only blue-colored bird with a red breast. The females tend to be of paler, duller coloration. The bird feeds mostly on insects.

The male mountain bluebird is entirely blue and is about $5\frac{1}{2}$ inches (14 centimeters) in length. Although it has been observed up to 12,000 feet (3660 meters), it usually is not found at elevations exceeding 5000 feet (1525 meters). The bird has a soft, sweet, whistle-like song at dawn.

The Florida bluebird (*S. s. grata*) ranges over the southern half of that state.

BLUEBOTTLE *(Insecta, Diptera).* Large flies of shining blue, green, or purple color. They lay their eggs on meat and other foods and so are often seen in dwellings.

BLUEGILL *(Osteichthyes).* A fish (*Helioperca incisor*) related to the sunfishes and bass. See also **Bass (Osteichthyes)**. Widely distributed east of the Rocky Mountains in lakes and the quieter parts of streams, the bluegill is esteemed as a pan fish. The fish attains a length of 10 inches (25 centimeters) or more, but in well-fished waters, rarely reaches this size. Although small, the fish readily rises to a fly and thus ranks among desirable game fishes.

BLUE GLOW. A type of luminescence emitted by certain metallic oxides, when heated. A blue glow is normally seen in electron tubes containing mercury vapor, arising from the ionization of the molecules in the mercury vapor.

BLUE *(Insecta, Lepidoptera).* Butterflies whose prevailing color is bright blue. The females are usually less blue than the males and some few species are not blue. With the coppers and hair-streaks they constitute the family *Lycaenidae*.

These insects are of European origin, but are now found almost worldwide. They are most abundant in the tropics. They are quite small and fragile. Their caterpillars are shaped like a sowbug, short, fat, and sometimes appear like a slug. Ants are known to defend them. The caterpillars often live in ants' nests, to which they are transported by the ants. A welcome exchange of food is the result; the ants like the caterpillar's honeydew; the caterpillars like ant larvae.

There are several hundred species of Blues. However, all species are not blue in color. Some are orange with blue spots. Among the females, many are brown or white and brown. The smallest is the pigmy Blue (*Brephidium exilis*). From wing tip to wing tip, this butterfly is only a little more than one-quarter inch (6 millimeters) in spread. The pigmy Blue exists in both North and South America.

BLUE JETS. Weakly luminous upward propagating discharges, blue in color, emanating from the tops of thunderstorms. Following their emergence from the top of the thundercloud, they typically propagate upward in narrow cones of about 15° full width at vertical speeds of roughly 100 $\mathrm{km\,s^{-1}}$ (Mach 300), fanning out and disappearing at heights of about 40–50 km (25–31 miles). Their intensities are on the order of 800 kR near the base, decreasing to about 10 kR near the upper terminus. These correspond to an estimated optical energy of about 4 kJ, a total energy of about 30 MJ, and an energy density on the order of a few millijoules per cubic meter. Blue jets are not aligned with the local magnetic field.

AMS

BLUE MOON. Those rare occasions when the moon takes on a markedly blue cast. Because of the rarity of blue moons, the phrase, "once in a blue moon," has been used metaphorically since the mid nineteenth century to denote a real, but rare event.

According to modern folklore, a Blue Moon is the second full moon in a calendar month. Usually months have only one full moon, but occasionally a second one sneaks in. Full moons are separated by 29 days, while most

months are 30 or 31 days long; so it is possible to fit two full moons in a single month. This happens every two and a half years, on average.

Usually, when the moon (or sun) is seen low in the sky or even high in a polluted one, it is yellowish or reddish. This is a consequence of the greater extinction of short wavelength radiation by small particles and molecules. Yet, there are particle sizes for which extinction is greater for long wavelengths, and the moon seen through a sky populated by such particles is bluish. It is rare that a large population of the particles of the appropriate size (and only that size) are produced, so the blue moon is very rare. In 1883 an Indonesian volcano named Krakatoa exploded. Scientists liken the blast to a 100-megaton nuclear bomb. Fully 600 kilometers (373 miles) away, people heard the noise as loud as a cannon shot. Plumes of ash rose to the very top of Earth's atmosphere. And the moon turned blue.

Krakatoa's ash is the reason. Some of the ash-clouds were filled with particles about 1 micron (one millionth of a meter) wide — the right size to strongly scatter red light, while allowing other colors to pass. White moonbeams shining through the clouds emerged blue, and sometimes green.

Blue moons persisted for years after the eruption. People also saw lavender suns and, for the first time, noctilucent clouds. The ash caused "such vivid red sunsets that fire engines were called out in New York, Poughkeepsie, and New Haven to quench the apparent conflagration," according to volcanologist Scott Rowland at the University of Hawaii.

Other less potent volcanos have turned the moon blue, too. People saw blue moons in 1983, for instance, after the eruption of the El Chichon volcano in Mexico. And there are reports of blue moons caused by Mt. St. Helens in 1980 and Mount Pinatubo in 1991.

One of the best-documented occurrences this century happened during September 1950, and caused a storm of flying saucer reports from Canada to England. "The skies took on strange colors; there was an eerie sort of light, followed in some places by almost complete darkness. . .. Shades varying from pink and orange to yellow and brown were used to describe the sky. . .. The sun disc when visible appeared blue or purple. As it appeared and disappeared through breaks in the clouds it seemed to be in motion — hence the basis for the impression of flying saucers." The incident was reported thus in the scientific journal, *Weather*.

Blue, green or lavender suns and moons, like blue skies, owe their color to scattering of light in the atmosphere. The difference is in the size of the particles doing the scattering. The sky is blue because the molecules of air are much smaller than the wavelength of visible light. Blue light has a shorter wavelength than red, and reacts more strongly with the tiny molecules than red does. The blue light is thus scattered more than red, and we see the scattered light of the sky as blue and the sun as reddish (especially when it is low in the sky and must pass through a lot of air to reach our eyes). The effect is called Rayleigh scattering, and it is responsible for what is called Tyndall blue. Blue eyes, some blue feathers, and the bluish color of the veins in your skin are all due to Rayleigh scattering.

Particles that are much larger than the wavelength of light scatter all wavelengths about equally. Clouds and snow are made up of particles several times larger than the wavelength of light, and they look white.

Blue suns and moons and pinkish skies occur when there are particles in the air whose size is just a little larger than the wavelength of light. These particles can resonate with light so that certain wavelengths are strongly scattered, while others are only affected about half as strongly. Oily droplets about 1 micrometer (a twenty-five thousandth of an inch) across, for instance, will scatter red light strongly, while letting blue light pass through — just the opposite of Rayleigh scattering.

"On September 23, 1950, several muskeg fires that had been quietly smoldering for several years in Alberta suddenly blew up into major — and very smoky — fires," writes physics Professor Sue Ann Bowling of the University of Alaska. "Winds carried the smoke eastward and southward with unusual speed, and the conditions of the fire produced large quantities of oily droplets of just the right size (about 1 micron in diameter) to scatter red and yellow light. Wherever the smoke cleared enough so that the sun was visible, it was lavender or blue. Ontario and much of the east coast of the U.S. were affected by the following day, but the smoke kept going. Two days later, observers in England reported an indigo sun in smoke-dimmed skies, followed by an equally blue moon that evening."

Forest fires are not the only possible producers of blue suns. Fine, far-travelled dust has been known to produce the same effect. So has volcanic ash, and many of the scientific articles written about the blue sun of September 1950 mentioned also the strange optical effects produced by the eruption of the volcanic island of Krakatoa a century ago. The important point is the particles in the atmosphere must all be very close to the same size, and that size must be about a micrometer across — a combination of circumstances that occurs literally once in a blue moon.

Over the next twenty years there will be a total of 17 blue moons, with an almost equal number of both types of blue moons occurring. No blue moon of any kind will occur in the years 2006, 2011, 2014, and 2017.

The more recent phenomenon, where the blue moon is considered to be the second full moon in a calendar month, last occurred on July 31, 2004. Two full moons in one month may occur in any month out of the year except for February, which is shorter than the lunar cycle.

The other, older blue moon event, which happens when there are four full moons in a season, last occured in August 2005. Since this type of blue moon is reckoned according to the seasons, it can only occur in February, May, August, or November, about a month before the equinox or the solstice.

BLUETHROAT *(Aves, Passeriformes).* One species, *Luscinia (Cyanosylvia) svecica* is a European bird related to the warblers. It occurs sparsely in central Europe and is also found occasionally in North America, including Alaska. Its preferred habitat is the marsh, although it is found along streams and fresh-water lakes. A shy bird, it prefers the seclusion of reeds and willows along streams.

The bluethroat nests on the ground. The European species winter in Africa and southern Asia. The female and young birds have a pale blue plumage about the throat area. The feathers are black tipped. The tail is rusty-brown and is usually kept spread. The male is dark blue under its beak and over its breast, with a red spot over the beak. The feathers underneath are white with a narrow white streak running through the rusty brown plumage on its back. It is a warbler, with a gentle high-pitched tone. The bluethroat measures about 5 inches (13 centimeters) in length.

BLUFF BODY. An object immersed in fluid stream flow is said to be bluff (or blunt) if its shape promotes a rapidly increasing downstream pressure gradient in the streamline flow around it. A high adverse gradient assists the creation of a stagnation point. The streamline flow breaks loose from the surface of the body on either side, leaving a turbulent low-pressure wake. This wake causes the characteristically high drag of bluff bodies.

BLUMBERG, BARUCH SAMUEL (1925–). Baruch Blumberg is an American virologist and research physician who discovered the 'Australia antigen' of the hepatitis B virus.

The son of a New York City Lawyer, Blumberg received his undergraduate degree in physics from Union College in Schenectady, New York and began graduate work in mathematics at Columbia University before deciding to enter medical school, also at Columbia in 1947. After completing his medical training, he went to Oxford University and received a D Phil in biochemistry in 1957. From 1957 to 1964 he worked at the National Institutes of Health, Bethesda, and then joined the Fox Chase Cancer Center in Philadelphia as associate director of its Institute for Cancer Research. In 1977 he also accepted a position as professor of medicine and medical anthropology at the University of Pennsylvania Medical School. From 1988 to 1995 Blumberg also served as master of Balliol College at Oxford. He was appointed as the first director of the National Aeronautics and Space Administration's (NASA) new Astrobiology Institute, a consortium of research institutions and universities interested in investigating aspects of life in the universe.

Blumberg is perhaps best known for his work on Hepatitis B, and his discovery of the 'Australia antigen', for which he was named one of the winners of the 1976 Nobel Prize in Physiology or Medicine. During the 1960s he had embarked on a research project to study the variation in the protein antigens present in the blood of different individuals. While working with the blood of an American hemophiliac patient who had received several transfusions, he found that it contained antibodies against a unique protein that could be found in the serum sample from an Australian Aboriginal. At first this antigen was believed to be a serum protein and

was dubbed the 'Australia antigen'. However, Blumberg's investigations revealed that the protein appeared only in the blood of people who had previous exposure to a special form of hepatitis, then known as 'serum' or 'infectious' hepatitis (hepatitis B) to distinguish it from the food-borne disease (hepatitis A). This was an important finding because it enabled clinicians to diagnose this disease through serological tests, rather than having to isolate and cultivate the causative agent, the *Hepatitis B virus*, which remains a problematic virus to this day. The test also became one of the first methods to screen blood donations for the virus. See also **Liver** and **Virus**.

Following up on his discovery of the antigen, Blumberg also worked on developing a vaccine against Hepatitis B. The special feature of this vaccine that makes it particularly useful is that it provides protection to people who have been exposed to the virus but have not contracted the disease. Since it first became available in 1982, the Hepatitis B vaccine has been administered to millions of people, especially in Asia and Africa. Blumberg also conducted further investigations into the nature of the Hepatitis B virus and demonstrated its role in the development of liver cancer. Thus, an unforeseen advantage of the vaccine he helped develop was the reduction in the incidence of liver cancer in addition to hepatitis.

NEERAJA SANKARAN, Yale University, New Haven, CT

BLUMENBACH, JOHANN FRIEDRICH (1752–1840). Physician, anthropologist, naturalist, physiologist, historian and bibliographer, Johann Friedrich Blumenbach is generally regarded as the founder of physical and scientific anthropology. He first used the word ldquo;race" in 1775 to classify humans into five divisions: Caucasian, Mongolian, Ethiopian, American, and Malay. Blumenbach also coined the term "Caucasian" because he believed that the Caucasus region of Asia Minor produced "the most beautiful race of men". Both Carl von Linné (1707–1778) and Blumenbach stated that humans are one species, and the latter remarked on the arbitrary nature of his proposed categories. Blumenbach was also one of the founders of comparative anatomy and the first to lecture on the topic.

Johann Blumenbach was born in Gotha, the son of a well-to-do gymnasium (secondary school) teacher, Blumenbach studied medicine at Jena (1769–1772). He continued his studies at Göttingen, where Christian Wilhelm Büttner inspired and guided him in matters of natural history. In 1775, Blumenbach obtained his MD with a dissertation entitled *De generis humani varietate nativa* (On the Natural Varieties of Mankind), of which the much enlarged third edition of 1795, dedicated to Joseph Banks, formed the main pillar of his reputation in physical anthropology. Of particular note was his widely accepted classification of the human species into five races, each of which he depicted in the context of customs and physical environment in engravings that were added to his *Beyträge zur Naturgeschichte* (1790–1806). In 1776, Blumenbach was appointed an extraordinary professor of medicine and assistant curator of the Academic Museum in Göttingen, and two years later he was promoted to full professor. Using the traditionally close connections between Göttingen and London, and drawing in particular on the good will of Banks, Blumenbach succeeded in 1781 in acquiring for the Academic Museum many of the natural history objects collected during Captain James Cook's circumnavigation of the world. In 1788, he was appointed Court Physician to the British King. At the end of 1791 and the start of 1792 he spent two months in London, meeting Banks as well as others connected with the Royal Society and British Museum. He also cultivated good relations with scientists of other nationalities such as Georges Cuvier, visiting Paris in 1797. Under Blumenbach's curatorship, the contents of the Museum, especially the collections of human skulls, were significantly augmented. Among Banks' donations to Göttingen was an Australian duck-billed platypus, described and named by Blumenbach as *Ornithorhynchus paradoxus*. See also **Banks, Joseph (1743–1820)**; and **Cuvier, Georges Léopold Chrétien Frédéric Dagobert Baron de (1769–1832)**.

Blumenbach was a conscientious and highly effective lecturer, presenting his last and 118th lecture course on natural history during the winter semester of 1836–1837. In conjunction with his lecturing activities, Blumenbach wrote several influential textbooks. In 1779 he published *Handbuch der Naturgeschichte*, which was translated into several languages and by 1830 was into its 12th German edition. Blumenbach's *Institutiones physiologicae* of 1787, with a 4th edition in 1821, was also translated into different languages. The English edition, *Elements of Physiology* of 1814, made printing history by being the first fully mechanically produced book. A widely discussed treatise by Blumenbach was his *Über den Bildungstrieb und das Zeugungsgeschäfte* (1781; 3rd Edition 1791) in which he put forward novel arguments in favor of epigenesis. See also **Physiology (The History)**.

Blumenbach's greatness consisted first and foremost in his effectiveness as a university teacher. A genial and self-confident man, he exerted a considerable influence on successive generations of students, attracting many to his interests in natural history and inspiring several pupils to undertake journeys of scientific exploration. Through an extensive network of correspondence, he helped establish Göttingen University as a major centre of academic science. Among his well-known correspondents were, in addition to Banks and Cuvier, Charles Bonnet and Petrus Camper. His marriage in 1778 to Louise Amalie Brandes made him the son-in-law of Georg Brandes, who held a powerful administrative position at Göttingen, and brother-in-law of Christian Gottlieb Heyne, the classics scholar and librarian; these family ties helped place him at the ruling centre of the University. See also **Bonnet, Charles (1720–1793)**.

BLUSHING. A term applied to a surface opacity or turbidity of varnish and lacquer films. The cause of this defect is commonly rapid evaporation of solvent, or improper formulation of the product.

BOA CONSTRICTOR. See **Snakes**.

BOARD FOOT. See **Units and Standards**.

BOBOLINK *(Aves, Passeriformes).* A widely distributed North American bird *Dolichonyx oryzivorus*, of which the male, marked with black, white, and yellow feathers, is conspicuous in the prairies and meadows where the species breeds. The female is duller and plainer. The bobolink is noted for its cheerful song.

BODE'S RELATION. In the latter part of the eighteenth century, an empirical relationship was noticed between the mean distances of the various planets from the sun. This relationship was first published by Bode, in 1772, and has since become known as Bode's relation in spite of the fact that there is certain evidence that it was known and used by Titus a number of years previous to the time of its announcement.

Bode's relation may be stated as follows: write down a series of 4's; to the first, add 0; to the second, add 3; to the third, add $6 = 3 \times 2$; to the fourth, $12 = 6 \times 2$; to the fifth, $24 = 12 \times 2$, etc.; the resulting numbers divided by 10 will give the approximate mean distances of the planets from the sun in astronomical units. The sequence is as follows:

Planet	Bode Distance	Mean Distance
Mercury	$4 + 0 = 4$	0.39
Venus	$4 + 3 = 7$	0.72
Earth	$4 + 6 = 10$	1.00
Mars	$4 + 12 = 16$	1.52
	$4 + 24 = 28$	
Jupiter	$4 + 48 = 52$	5.20
Saturn	$4 + 96 = 100$	9.54
Uranus	$4 + 192 = 196$	19.18
Neptune	$4 + 384 = 388$	30.06
Pluto	$4 + 768 = 772$	39.4

The value in the last column is the actual mean distance of the planet from the sun in astronomical units. Thus Bode's relation has the form

$$D = A + BC^n$$

where $A = 0.4$, $B = 0.3$, $C = 2$, and $n = -\infty$, 0,1 2, 3, ... and yields the distance in astronomical units.

At the time that the relation was first proposed, the gap between Mars and Jupiter was not filled and no planets were known outside of Saturn. The

relation predicted distances, and when Uranus was discovered with mean distance so close to the predicted value, Bode's relation was believed to be established. The discovery of the asteroid Ceres, with a mean distance of 2.77, gave further support to the validity of the relation. It is interesting to note that, in making the computations that led to the discovery of Neptune, Adams used the predicted Bode distance for the then unknown object.

During the nineteenth century, many unsuccessful attempts were made to place Bode's relation upon a theoretical foundation. The failure of the law in the cases of Neptune and Pluto has convinced most astronomers that the relation is a purely empirical relationship, more in the realm of coincidence than an actual physical law.

BODY-CENTERED STRUCTURE. A type of crystal structure, in which atoms are located at the corners and center of a cubic or rectangular cell.

BODYING AND BULKING AGENTS (Foods). These terms tend to be self-defining. Additives in these classifications are frequently described together because many substances will serve one or both purposes.

Bodying Agents. The *body* of a food substance is generally associated with the textural qualities of the substance, notably with mouth-feel or chewiness. Some food products, particularly those of a fabricated nature, may possess a full complement of desirable consumer appeals (taste, odor, color, nutritive value, etc.) and yet lack the desirable textural quality of body. Thus, soups, gravies, sauces, cheese foods and spreads, dressings, snack dips, and margarines, among others, can be improved through the addition of bodying agents. For example, formulations for frozen desserts can be improved in this respect by the addition of low levels of a material such as microcrystalline cellulose (about 0.25% weight), in combination with soluble hydrocolloids, such as guar, locust bean gum, alginates, or carrageenans. See also **Gums and Mucilages**.

Bulking Agents. These substances are added to semiliquid and solid food products to add bulk to the end product over and beyond the bulk resulting from the strict use of conventional ingredients.

For example, the natural sugars (sucrose, fructose, etc.) are best known for their contribution of sweetness to food products. The sugars, however, also perform other useful functions, including their natural preservative qualities and, in many foods such as baked goods, contribute considerable bulk to the finished product. As described under **Sweeteners**, a number of artificial, non-carbohydrate compounds serve as excellent sweeteners, but they lack the ability to achieve the desired bulk.

Microcrystalline Cellulose. This additive achieves about the same degree of body and substance in frozen desserts that is normally achieved only in well-emulsified products with a 2–4% higher fat content. This is the result of the ability of microcrystalline cellulose to stabilize the serum solid. Microcrystalline cellulose imparts body and smoothness to ice cream and ice milk, and tends to make them less "cold tasting." There are no off-flavors associated with the substance and frozen desserts melt to smooth, creamy consistencies. Bodying agents play an effective, if not exclusive role, in improving freeze-thaw properties of numerous products. In another example, when whey or sugar solids are used to reduce or replace portions of the milk solids nonfat (MSNF), there is a definite loss of functionality of the mix, resulting in reduced body and texture. Problems, such as stickiness, gumminess, and weak body can be corrected by the addition of a bodying agent, such as microcrystalline cellulose, in a very small amount (0.25–0.4% weight).

When microcrystalline cellulose is used to add bulk to the end product, the bulk not only may be compensated for the lack of a natural bulking agent, but may add extra bulk. In addition to achieving the natural characteristics expected of a product, there are two additional advantages: (1) The cellulose increases the fiber content of a food product, and (2) weight is added, thus reducing the effective caloric content (caloric density) of a given weight serving of a product. However, it should be stressed that microcrystalline cellulose is only a partial substitute for fat, which is needed for air entrapment, or for flour, which provides the elastic gluten structure.

In the currently very important field of manufacturing low-calorie foods, a bulking agent essentially can be considered as a diluent even though it may play other important roles. Thus, the diet-conscious consumer can eat cookies, doughnuts, or portions of cake of traditional size and yet consume considerably fewer calories. The important factor in selecting a bulking agent for low-calorie foods is that of finding a substance that combines non-caloric qualities with other functional capabilities so that lower amounts of relatively high-calorie ingredients can be reduced or replaced without detracting drastically from the consumer appeals of the finished product.

Isomalt. An odorless, white, sweet-tasting, crystalline, practically non-hygroscopic substance is used in a wide variety of confectionery products, such as chocolates, caramels, hard candy, tablets, pan-coated products, and chewing gum. The low hygroscopicity simplifies packaging requirements. For baking, isomalt can be substituted for sucrose on a 1:1 basis. Although used in fruit-flavored products, it has not been used in traditional jelly and preserves. Isomalt can be used as a substitute for sucrose in ice cream, ice milk, yogurt, and a variety of desserts and fillings. For tabletop sweeteners, isomalt can be used in combination with saccharin, cyclamates, aspartame, acesulfame-K, and some other artificial sweeteners.

Isomalt (*Palatnit*^{R}) was developed in Germany and has been well accepted in Europe. A sucrose-glucosylfructose-mutase from *Protaminobacter rubrum*, a nonpathogenic organism found in beet sugar factories, is used to transform sucrose into the reducing sugar isomaltose. The properties of isomalt coincide well with existing food processing equipment and procedures.

Oat Bran. Fat replacement is a very timely topic in the food processing industry as of the early 1990s, and is also described in other articles of this *Encyclopedia*. Check Alphabetical Index.

As pointed out by Pszczola, certain fat replacers, when used with 90% fat-free ground beef or pork sausage, can provide the texture, flavor, and juiciness of full-fat meat products. One fat replacer is specially processed oat bran, with added flavorings and seasonings. It is estimated that up to 20% of the ground beef sold in the near future will be of the low-fat variety. (Total consumption of ground beef in the United States is estimated at about 7 billion pounds (3.2 billion kg) annually!) It is reported that, after 3 years of research by the Webb Technical Group (consultants sponsored by the Beef Industry Council of the National Live Stock and Meat Board), oat brain was selected above other substances studied. These included wheat bran, psyllium husk, rice bran, barley bran, vegetable protein, soy fiber, cane fiber, and carrageenan. As reported, the advantages of oat bran include:

1. Keeps meats from drying out when cooked;
2. Good mouth-feel that imitates fat;
3. Lack of a cereal flavor;
4. Retention of natural meat flavoring; and
5. A holding time superior to other fat replacers.

Thus far, all ingredients in the replacer are considered GRAS (Generally Regarded as Safe) and have FDA (U.S.) approval.

Classification of Fat Substitutes. The development of suitable fat substitutes or replacers will remain a very active field for the foreseeable future. Experts have classified fat substitutes into several categories:

1. *Protein-based substitutes*, the present major limitation being that such substitutes do not lend themselves to use in cooking oils or with products that require frying or baking, because excessive heat causes the ingredients to coagulate, with loss of fat-like mouthfeel.
2. *Synthetic, fat-like substances* that are resistant to hydrolysis by digestive enzymes. One type is a mixture of the hexa-to-octaesters of sucrose; others are esterified propoxylated glycerols and dialkyl dihexadecylmalonate (DDM), which has been used in potato and tortilla chips; trialkoxytricarballate-tricarballic acid esterified with fatty alcohols, currently under trial for use in margarine- and mayonnaise-type products.
3. *Carbohydrate-based substitutes*, which include *Gums*, sometimes referred to as hydrophilic colloids or hydrocolloids. These are long-chain, high–molecular weight polymers that dissolve or disperse in water, providing a thickening, sometimes gelling, effect. The period of usage of these substances dates back to the early 1980s. They include:
   a. *Corn starch maltodextrin*, which is a non-sweet saccharide polymer produced by a limited hydrolysis of corn starch;
   b. *Potato starch maltodextrin*, rather widely used for bakery products, dips, salad dressings, frosting, frozen desserts, mayonnaise-like products, meat products, and confections;
   c. *Tapioca dextrins*, used in a number of products and, more recently, in microwavable cheese sauces;

d. *Konjac Flour*, a product of the konjac root traditionally has been used by the Japanese and other Far East nations for over a thousand years to make gels and noodles that are stable in boiling water. Products range from chewy desserts to colored soup dumplings. Konjac was first used in the United States in the early 1900s. Konjac flour is the dried, pulverized, and winnowed tubers of the perennial herb *Amorphophallus konjac*. The dried tuber contains up to 60–80% konjac flour. Because of its interaction with carrageenan and starches to form heat-stable gels, the potential of konjac flour as a fat substitute is promising.

It is important to mention that combinations of some of the aforementioned products are available to food processors. Over the years, for certain special products, including pharmaceuticals, glycerin, methylcellulose, polyvinylpyrolidon (PVP), sodium carboxymethycellulose, and whey solids have been used.

BOERHAAVE, HERMAN (1668–1738). Herman Boerhaave was a Dutch physician, chemist and botanist whose teachings helped shape medical school curricula throughout Europe.

Although he is not remembered for producing his own original theories or discoveries, few individuals exercised such far-reaching influence on eighteenth century European medicine as Herman Boerhaave. As a professor of medicine, chemistry and botany at the University of Leyden's medical school, Boerhaave's fame attracted students and correspondents from across the continent. In addition, his textbooks on medicine and chemistry went through literally hundreds of editions in half a dozen languages and remained standard works at colleges around Europe for many decades.

By contrast, Boerhaave's early years were rather modest. The son of a pastor, he took his first degree in philosophy at Leyden in 1690 and then embarked on theological studies before beginning to read medical texts on the side. Whilst he is not known to have ever attended lectures in medicine, he successfully passed the exam for a medical degree at the University of Harderwijk in 1693 and afterward began giving private classes in Leyden on mathematics, chemistry and medicine until a chair in botany became available at the university in 1709.

The most distinguishing feature of Boerhaave's medical thought was his systematic combination of reverence for ancient teachings with analysis of the latest findings in anatomy, chemistry and physiology. He emphasized the new mechanical philosophies for understanding the body's movements and structures, yet also praised traditional Hippocratic writings for their explication of medical practice. Boerhaave's teaching program subsequently became enormously influential in establishing new curricula at universities such as Edinburgh, Göttingen and Vienna, where prominent former students including Albrecht von Haller and Alexander Monro held faculty posts. BOG. A waterlogged, spongy groundmass, primarily mosses, containing acidic, decaying vegetation, which may develop into peat. Also, the characteristic vegetation of this environment, especially sphagnum, sledges, and heaths. A synonym is *peat bog*. See also **Muskeg**.

BOG LAKE. A relatively small body of open water surrounded or nearly surrounded by bogs and characterized by a false bottom of organic (peat-like) material, high acidity, scarcity of aquatic fauna, and vegetation growing on a firm deposit or on a semi-floating mat of peat.

BOHOROK. See **Winds and Air Movement**.

BOHRIUM. See **Chemical Elements**; and **Chemical Elemets: The History of the Origin**.

BOHR MAGNETON. A unit of magnetic moment used in atomic physics, defined as

$$\mu_{\mathrm{B}} = e/h4\pi m_e c = 9.27 \times 10^{-24} \text{ ampere-meter}^2$$

in which e is the electronic charge in coulombs, h is Planck's constant, and m_e is the rest mass of the electron. If the angular momentum of an orbiting electron in an atom is $L = l^*/h2\pi$, the magnetic moment established by the orbital motion of the electron is $\mu_{l^*} = l^*\mu_B$. The measured magnitude μ_s of the spin magnetic moment of an electron is, however, $2s\mu_B$, such that its gyromagnetic ratio is twice that for the orbital motion. A dimensionless multiplicative factor, called a g-factor, is introduced in the relationship that expresses the measured magnetic moment in terms of Bohr magnetons such that the spin magnetic moment of an electron is $\mu_s = gs\mu_B$, in which $g = 2$. A comparable insertion of a g-factor in the formula for the orbital magnetic moment of an electron leads to $g = 1$. See **Nuclear Magneton**.

BOHR, NIELS HENRIK DAVID (1885–1962). Bohr was a Danish physicist who is recognized for revolutionizing atomic theory. Bohr studied physics at the University of Copenhagen. In 1907, Bohr was awarded a gold medal for an essay on the surface tension of water by the Royal Danish Academy of Sciences and Letters. In 1911 he finished his doctoral dissertation on the electron theory of metals.

After his studies, Bohr worked under Rutherford, who had published the theory that the atom consisted of a central nucleus orbited by electrons. By 1912, Bohr returned to University of Copenhagen and by 1913 he published a trilogy of papers that deeply impressed Einstein and other scientists. In the papers, he departed from classical mechanics and made use of Planck's constant and the quantum theory. At age 28, Bohr reached the summit of his career with his theory of the atom. His model was an atom in which electrons moved around the nucleus in different orbits. He suggested atoms emit electromagnetic radiation when electrons move from one energy level to another. In 1922, Bohr won the Nobel Prize for physics for this work.

In the 1930's, Bohr pointed out, that particles, protons, and neutrons were strongly coupled together. This picture of a compound nucleus had a great influence on the theory of nuclear reactions.

After Hitler took power in Germany, Bohr offered help to many escaping Jewish scientists. Later, he donated his Nobel gold medal to the Finnish war effort. When the German army occupied Denmark and planned to arrest him so they could make him work on an atomic project, Bohr and his family fled to Sweden. Eventually Bohr and his son made it to the United States. Bohr spent time at Los Alamos where he made some technical contributions to the development of the first atomic bomb.

Bohr's main interest was always the implications of atomic bombs for the future. Bohr organized the Atoms for Peace Conference in Geneva in 1955. In 1957 Bohr received the Atoms of Peace Award. He is also remembered for helping to establish CERN, Europe's great particle accelerator and research station. Also to his credit is the Bohr Institute for Theoretical Physics, an institute that welcomes the most famous physicists in the world to its laboratories and conferences.

See also **Bohr Magneton**; and **Bohr Theory of Atomic Spectra**.

J. M. I.

BOHR THEORY OF ATOMIC SPECTRA. Bohr based his theory of atomic spectra upon two postulates: Postulate 1. "An atomic system can, and can only, exist permanently in a certain series of states corresponding to a discontinuous series of values for its energy; hence, any change in the energy of the system, including emission and absorption of electromagnetic radiation, must take place by a complete transition between two such states. These states will be called the stationary states of the system." Postulate 2. "That the radiation absorbed or emitted during a transition between two stationary states is monochromatic and possesses a frequency v, given by the relation $hv = E_2 - E_1$," where h is the Planck constant and E_1, E_2 are

energies of the two stationary states. See also **Atomic Spectra**; **Quantum Mechanics**; and **Quantum Theory of Spectra**.

BOILER (Steam Generator). In a modern steam generator, various components are arranged to absorb heat efficiently from the products of combustion. These components are generally described as boiler, superheater, reheater, economizer, and air heater. In addition to thermal and mechanical efficiency, the boiler designer must consider both the impact of environment controls and the purpose for which the steam is generated — for powering turbines in the production of electricity, for processing use, as in a chemical plant (steam heat, reactions, etc.), or for the combined objectives of power production and process use, the latter frequently referred to as *cogeneration*.

Principal Types of Boilers

Boiler surface may be defined as those parts of tubes, drums and shells which are part of the boiler circulatory system and which are in contact with the hot gases on one side and water or a mixture of water and steam on the other side. Although the term boiler may refer to the overall steam-generating unit, the term "boiler surface" does not include the economizer or any component other than the boiler itself. Boilers may be broadly classified as shell, fire-tube and water-tube types.

Modern boilers are of the water-tube type. The safety and dependability of operation that characterize the boilers of today had their beginning in the introduction of this boiler type. In the water-tube boiler, the water and steam are inside the tubes, and the hot gases are in contact with the outer tube surfaces. The boiler is constructed of a number of sections of tubes, headers and drums joined together in such a way that circulation of water is provided for adequate cooling of all parts, and the large indeterminate stresses of the fire-tube boilers are eliminated. With water-tube designs it is possible to protect thick drums from the hot gases and resultant high thermal stresses. With correct operation, explosive failures have been essentially eliminated with water-tube boilers. Further the water space is divided into sections so arranged that, should any section fail, no general explosion occurs and the destructive effects are limited.

The water-tube construction facilitates obtaining greater boiler capacity, and the use of higher pressure. In addition, the water-tube boiler offers greater versatility in arrangement and this permits the most efficient use of the furnace, superheater, reheater, and other heat recovery components.

Water-tube boilers may be classified as straight-tube and bent-tube. Straight-tube boilers have been supplanted by modern designs of bent-tube boilers, which are more economical and serviceable than the straight-tube designs.

The majority of fossil fuel steam generators and commercial nuclear steam supply systems operate at subcritical pressures. A comprehension of the boiling process is essential in the design of these units.

Departure from Nucleate Boiling (DNB). The point of departure from nucleate boiling is described and illustrated in the entry on **Boiling**. The illustration in that entry shows the various heat transfer regimes taking place along the length of a uniformly heated vertical tube cooled by water flowing upward. On this figure, the inner wall temperatures are plotted as functions of enthalpy and steam quality, starting with hot water, passing through the region where steam is being generated (0 to 100% quality), and finally into the superheated region.

By following the line for moderate heat flux it is seen that the metal temperature in the subcooled region is parallel to the water temperature, and only slightly above it. When boiling starts, the heat transfer coefficient increases and the metal temperature remains just above saturation temperature. Finally, at high steam quality, the DNB point is reached where the nucleate boiling process breaks down. The metal temperature increases at this point but decreases again as steam quality approaches 100%. In the superheat region the wall temperature again increases with, and approximately parallel to, the superheated steam temperature.

For the curve marked "high heat flux," the DNB point is reached at a lower steam quality, and the peak metal temperature is higher. At very high heat fluxes the DNB occurs at low steam quality and the metal temperature would be high enough to melt the tube if it were able to withstand the internal pressure without first plastically deforming and rupturing. At extremely high heat fluxes, DNB can occur in subcooled water. Avoidance of this last type of DNB is an important criterion in the design of nuclear reactors of the pressurized-water type.

Figure 1 presents the DNB phenomenon from the standpoint of a heated flow channel in which flow, pressure, and inlet temperature (inlet subcooling) remain constant. DNB is also affected by variations in mass velocity, pressure, subcooling and channel dimensions.

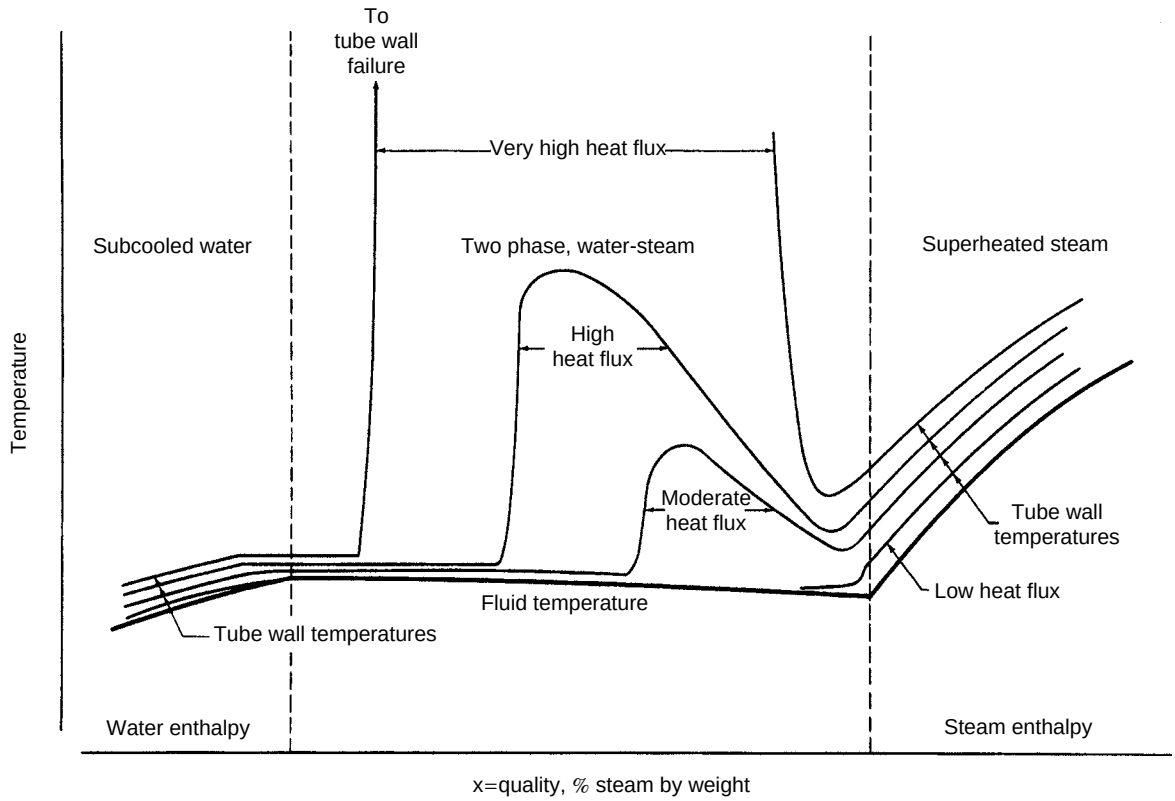

Fig. 1. Fluid and tube wall temperatures under conditions of water heating, nucleate boiling, and superheating steam.

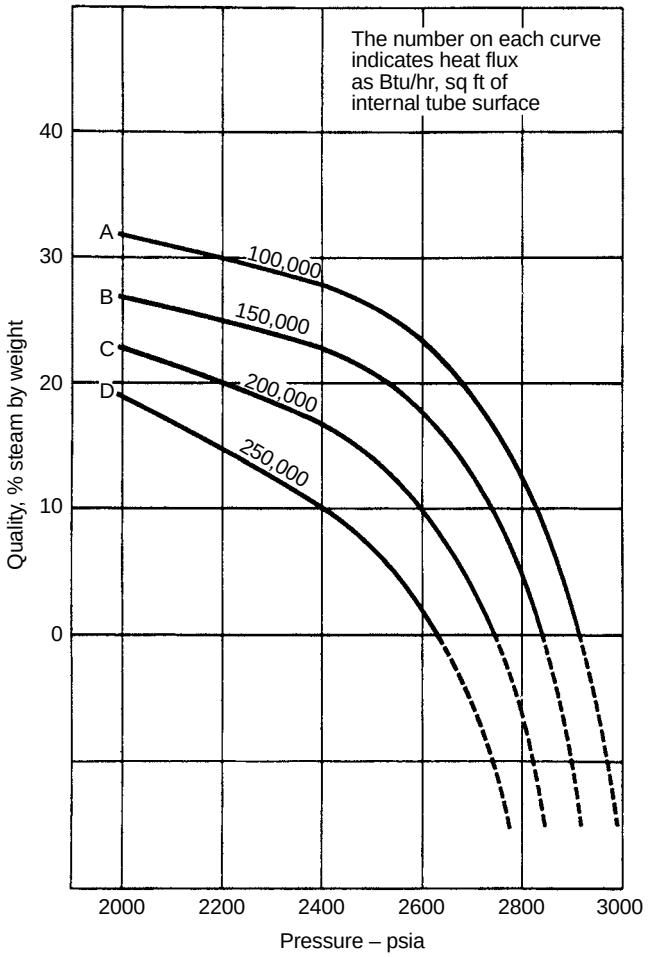

Fig. 2. Steam quality limit for nucleate boiling as a function of pressure.

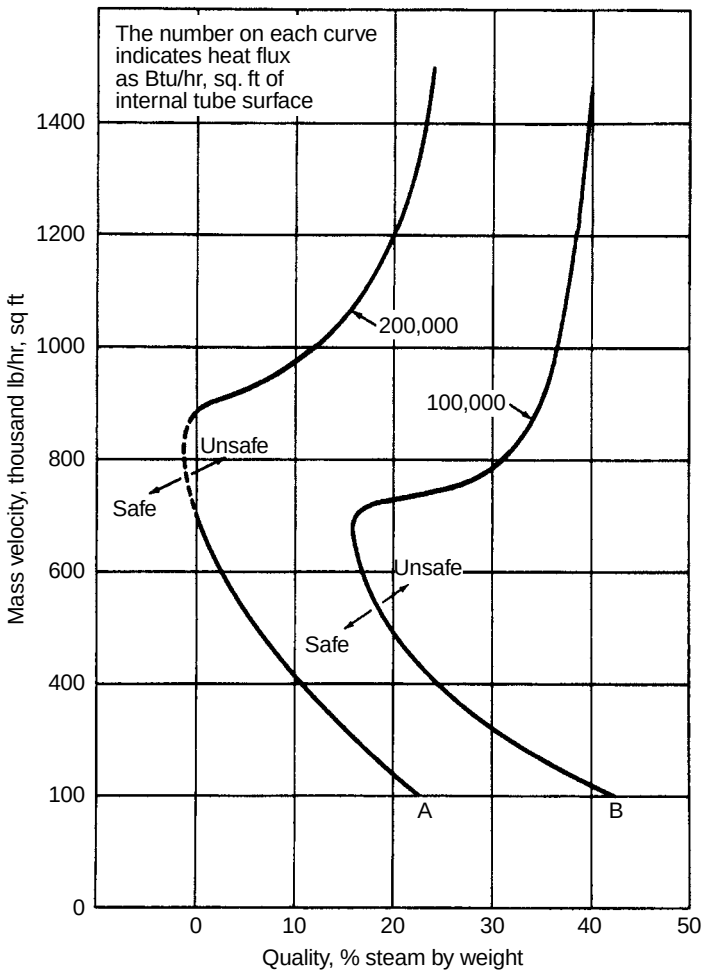

Fig. 3. Steam quality limit for nucleate boiling at 2700 psi (184 atm), as a function of mass velocity.

Many fossil-fuel boilers are designed to operate in the range between 2000 psi (136 atmospheres) and the critical pressure. In this range, pressure has an important effect, shown in Fig. 2, in that the steam quality limit for nucleate boiling falls rapidly near the critical pressure, i.e., at constant heat flux the DNB point occurs at a decreasingly low steam quality as pressure rises. Many correlations of critical heat flux or DNB have been proposed, and are satisfactory within certain limits of pressure, mass velocity and heat flux. Figure 3 is an example of a correlation that is useful in the design of fossil-fuel natural-circulation boilers. This correlation defines safe and unsafe regimes for two heat flux levels at a given pressure in terms of steam quality and mass velocity. Additional factors must be introduced when tubes are used in membrane or tangent walls or in any position other than vertical. Such factors include inside diameter of tubes and surface condition. The last of these, where the character of the inside tube surface is purposely altered, will be discussed further in the section on "Ribbed Tubes."

The preceding discussion applies only to subcritical pressures. As the operating pressure is increased the various flow and boiling regimes gradually disappear. However, there are tube metal temperature excursions in low-velocity supercritical-pressure operation similar to those found in subcritical boiling. This phenomenon, known as pseudo-film boiling, is currently under intensive experimental investigation.

Ribbed Tubes. Since the 1930s, a large number of devices, including internal twisters, springs, and various grooved, ribbed, and corrugated tubes, to inhibit or delay the onset of DNB have been tried and tested. The most satisfactory overall performance was obtained with tubes having helical ribs on the inside surface.

Steam Separation and Purity. Boilers operating below the critical point, except for once-through types, are customarily provided with a steam drum in which saturated steam is separated from the steam-water mixture discharged by the boiler tubes. Saturated steam leaves, and feedwater enters this drum through their respective nozzles (with some exceptions in multidrum boilers).

However, the primary functions of this drum are to provide a free controllable surface for separation of saturated steam from water and a housing for any mechanical separating devices. Steam drums are designed to provide the volume necessary, in combination with the controls and firing equipment, to prevent excessive rise of water into the steam separators, resulting in carryover of water with the steam.

Solids in Boiler Water. Boiler water contains solid materials, mainly in solution. Steam contamination (solid particles in the superheated steam) comes from the boiler water, largely in the carryover of water droplets. Therefore, in general, as boiler-water concentration increases, steam contamination may be expected to increase.

Historically the carryover of water into superheater tubes resulted in deposit of entrained solids in the superheater tubes. This caused increased tube temperatures and distortion and burnout of tubes. Therefore, it was necessary to develop devices to remove water from the steam. The need for extreme purity of steam for use in modern high-pressure turbines has provided additional incentive for reducing the carryover of solids in steam. Troublesome deposits on turbine blades may occur with surprisingly low (0.6 ppm) total solids contamination in steam. See **Feedwater (Boiler)**.

Factors Affecting Steam Separation. Separation of steam from the mixture discharged into the drum from steam-water risers is related to both design and operating factors, some of which include:

Design factors

1. Design pressure
2. Drum size, length and diameter
3. Rate of steam generation
4. Circulation ratios — water circulated to heated tubes divided by steam generated
5. Type of arrangement of mechanical separators
6. Feedwater supply and steam discharge equipment and arrangement
7. Arrangement of downcomer and riser circuits in the steam drum

Operating factors

1. Operating pressure
2. Boiler load (steam flow)
3. Type of steam load
4. Chemical analysis of boiler water
5. Water level carried

In steam drums without separation devices, where separation is by gravity only, the manner in which some of the above items affect separation is indicated in simplified form in Figs. 4 and 5.

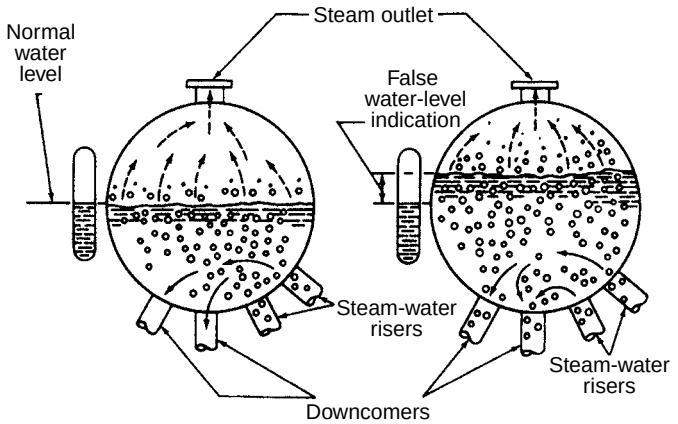

Fig. 4. Effect of rate of steam generation on steam separation in a boiler drum without separation devices.

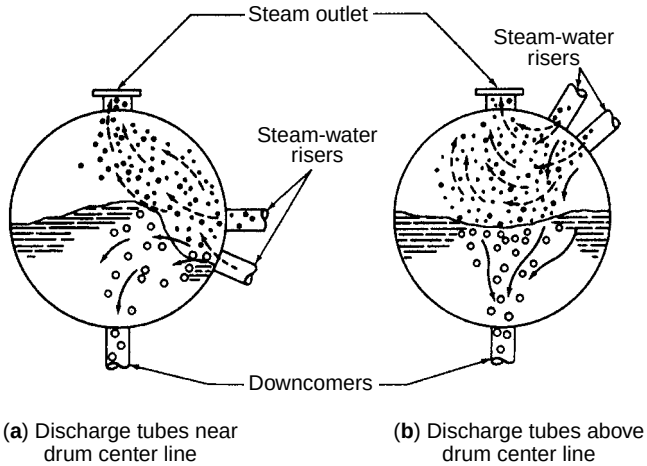

Fig. 5. Effect of location of discharge from risers on steam separation in a boiler drum without separation devices.

Mechanical Steam Separators for Drums. Gravity steam separation alone is generally unsatisfactory for boilers of the usual sizes and operating requirements. Most steam drums, therefore, are fitted with some form of primary separator. Simple types of primary separators are shown in Fig. 6. These devices facilitate or supplement gravity separation. The extent and arrangement of the various baffles and deflectors should always allow for access to the drums.

In a cyclone steam separator, centrifugal force many times the force of gravity is used to separate the steam from the water. Cyclones, essentially cylindrical in form, and corrugated scrubbers are the basic components of this type of separator.

The cyclones are arranged internally along the length of the drum, and the steam-water mixture is admitted tangentially. The water forms a layer against the cylinder walls, and the steam (of less density) moves to the core of the cylinder and then upward. The water flows downward in the cylinder and is discharged through an annulus at the bottom, below the drum water level. Thus, with the water returning from drum storage to the downcomers virtually free of steam bubbles, maximum net head is available for producing flow in the circuits, which is the important factor in the successful use of natural circulation. The steam moving upward from the cylinder passes through a small primary corrugated scrubber at the top of the cyclone for additional separation. Under many conditions of operation no further refinement in separation is required, although the cyclone separator is considered only as a primary separator.

When wide load fluctuations and variations in water analyses are expected, large corrugated secondary scrubbers may be installed at the top of the drum to provide nearly perfect steam separation. These scrubbers may be termed secondary separators.

The combination of cyclone separators and scrubbers described above provides the means of obtaining steam purity corresponding to less than 1.0 ppm solids content under a wire variation of operating conditions. This purity is generally adequate in commercial practice. However, further refinement in steam purification is required where it is necessary to remove boiler-water salts, such as silica, which are entrained in the steam by vaporization or solution mechanism. Washing the steam with condensate or feedwater of acceptable purity may be used for this purpose.

Steam Washing. It is often impractical to maintain boiler-water concentrations of silica sufficiently low to prevent turbine fouling, and other measures such as steam-washing are used to control this type of steam contamination.

In steam-washing, silica-laden steam is brought into intimate contact with relatively pure wash water, such as condensate or feedwater, and silica is absorbed from the steam by the fresh water.

A steam-drum arrangement employing steam washing is shown in Fig. 7. The drum is equipped with primary mechanical separators of the centrifugal type and corrugated scrubbers. Steam leaving the primary separators flows to a steam washer arranged in the top of the steam drum. The washer consists of a rectangular column approximately the length of the steam drum. Steam passes vertically upward through a perforated plate, a pack of stainless steel wire mesh, a second perforated plate, and finally a corrugated scrubber element. Wash water enters the drum through a nozzle and flows downward through the washer, counterflow to the steam. The steam velocity through the tray perforations maintains, above each tray, a

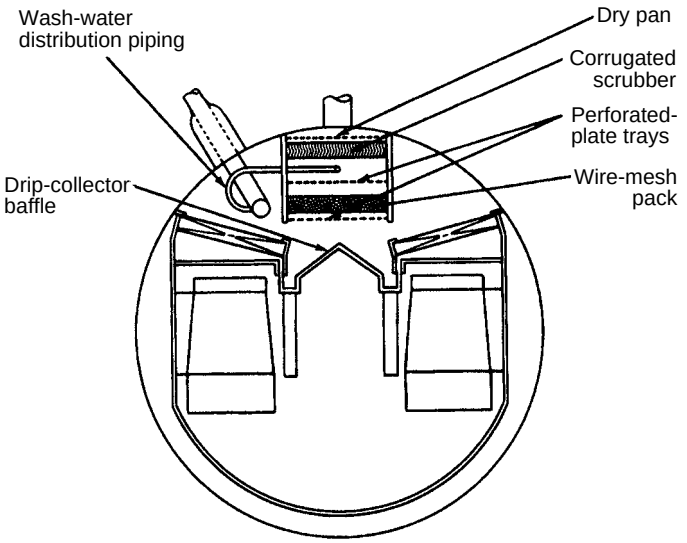

Fig. 7. Arrangement of steam-drum internals for washing silica-laden steam.

layer of wash water kept in violent agitation by the steam. The wire mesh provides a large surface area for achieving intimate contact between the steam and the wash water.

Bent-Tube Boilers

Many important modern designs of boilers, such as the two-drum Stirling, the Integral-Furnace, the Radiant, and the Universal Pressure are included in the "bent-tube" classification. All bent-tube boilers of contemporary design, with the exception of those with stoker or flat refractory floors, have water-cooled walls and floors or hoppers.

Integral-Furnace Boiler. This boiler is a two-drum boiler, which in the smaller capacities is adaptable to shop assembly and shipment as a package. Figure 8 shows a low-capacity Type Fm Integral-Furnace boiler designed for shop assembly. This package boiler is shipped complete with support steel, casing, forced-draft fan (unmounted in larger sizes), firing equipment, and controls — ready for operation when water, fuel, and electrical connections are made. Only a stub stack is required. It is built for outputs from 8000 to 160,000 pounds (3629 to 72,576 kilograms) of steam per hour. Steam pressures range to 925 psi (63 atmospheres) and temperatures to 441 °C. Units can be fired with oil, gas, or a combination of the two. Only a forced-draft fan is required, as the casing is airtight (welded) and the combustion gases are under pressure. Size of the unit is varied principally by changes in setting depth and drum length. Two combinations of width and height facilitate standardization of parts and assembly. An Integral-Furnace boiler after installation is shown in Fig. 9.

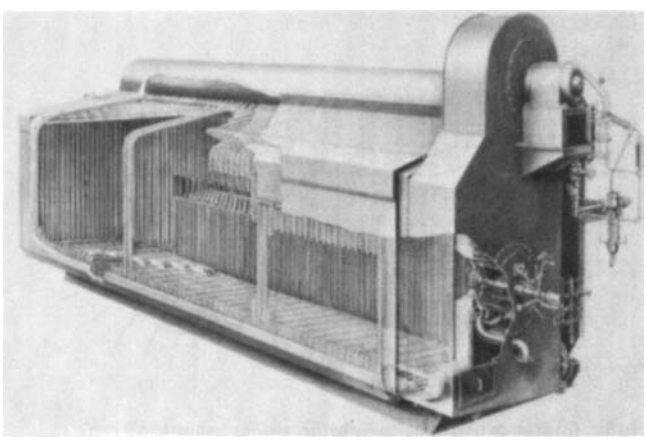

Fig. 8. Integral-furnace boiler. Shop-assembled unit, complete and ready to operate.

Two-Drum Stirling Boiler. The simple arrangement possible for the connecting tubes, with one upper steam drum directly over one lower drum, led to the development of a series of designs known as the two-drum Stirling boiler. Figure 10 shows a unit of this type for cyclone-furnace firing. These designs are standardized over a wide range of capacities and pressures, with steam flows ranging from 200,000 to 1,200,000 pounds (90,720 to 544,320 kilograms) per hour, design pressures up to 1750 psi (119 atmospheres), and steam temperatures up to 538 °C. The firing may be by cyclone furnace, pulverized coal, oil or gas.

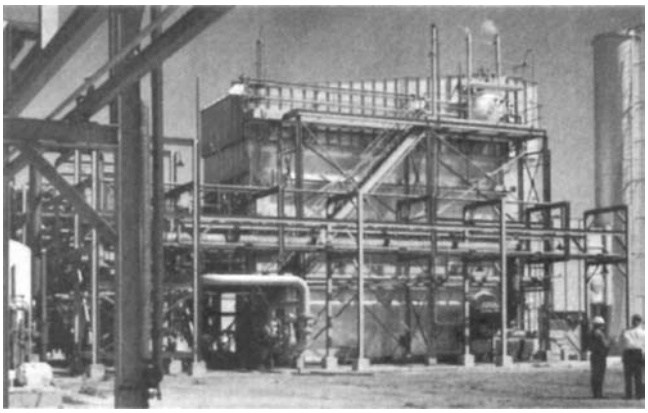

Fig. 9. Representative installation of an integral-furnace boiler.

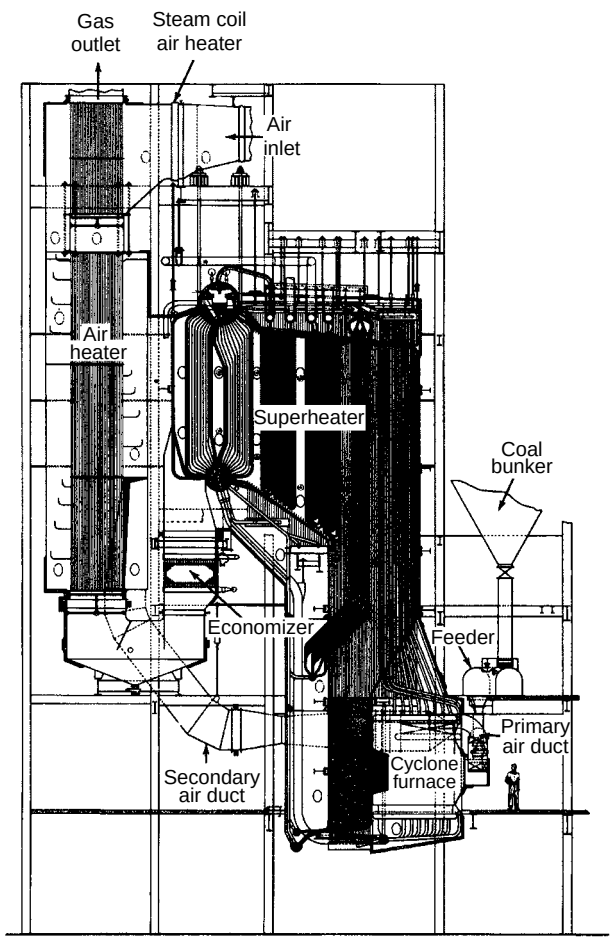

Fig. 10. Two-drum Stirling boiler for cyclone-furnace firing.

The two-drum Stirling boiler is furnished for industrial and utility applications. It may be considered as a transition unit, covering an intermediate size range. Because of its versatility and economy, the boiler enjoys worldwide acceptance.

High-Pressure and High-Temperature Boilers. In the rapid development of power-plant economy, the single-boiler, single-turbine combination has been adopted for the central station and where electric power is

the end product of heat transformation. There is an incentive to use very large electrical generators, since the heat rate, investment, and labor costs decrease as size increases. In the design of large boiler units for this application, the important factors are (1) high steam pressure, (2) high steam temperature, (3) bleed feedwater heating, and (4) reheat. High steam pressure means high saturation temperature and low temperature difference between steam and exit gas. High steam temperature means high initial temperature and, usually, reheating to high temperature for reuse of the steam. Bleed feedwater heating lowers the mean temperature difference in an economizer and increases the gas temperature leaving the economizer. An air heater is then required to lower the exit-gas temperature. These factors and, above all, the economic need for continuity of operation to realize an optimum return on the large investment involved have combined to produce boiler units different in many respects from earlier concepts. Thus the principle of the integrated boiler unit is firmly established for very large boilers, as well as for boilers of smaller outputs.

As steam pressures have increased, steam temperatures also have increased. This necessitates proportionally more superheating surface and less boiler surface. When pressures exceed 1500 psi (102 atmospheres) in a drum-type boiler, the heat absorbed in furnace and boiler-screen tubes is normally almost enough to generate the steam. Thus it is usually more economical to use economizer surface for any additional evaporation required as well as to raise the feed-water to saturation. All the steam is then generated in the furnace, water-cooled wall enclosures of superheater and economizer, boiler screen, division walls, and in some cases the outlet end of a steaming economizer as contrasted with only use of the boiler surfaces per se.

Radiant Boiler. This boiler is a high-pressure, high-temperature, high-capacity boiler of the drum type. It is adaptable to pulverized-coal or cyclone-furnace firing, and also to natural gas and oil firing. Boiler convection surface is a minimum in these units.

The radiant boiler may be a pulverized-coal-fired unit with hopper-bottom construction for dry-ash removal. It may be an output of 1,750,000 pounds (793,800 kilograms) of steam per hour for continuous operation. Design pressure is 2875 psi (196 atmospheres); and primary and reheat steam temperatures are 538 °C. Standard components (furnaces, superheaters, reheaters, economizers, and air heaters) are integrated to coordinate the fuel fired with the turbine throttle requirements. Standard sizes are available in reasonable increments of width and height to permit selection of economical units for the required steam conditions and capacity.

The El Paso-type radiant boiler is a standardized unit developed for natural gas and oil firing. This compact and economical design is suitable for these fuels because of the cleanliness of natural gas and the relatively minor ash problems encountered with oil as compared with coal.

Universal-Pressure Boiler. This is a high-capacity, high-temperature boiler of the "once-through" or "Benson" type. Functionally applicable at any boiler pressure, it is applicable economically in the pressure range from 2000 to 4000 psi (136 to 272 atmospheres). Firing may be by coal, either pulverized or cyclone-furnace-fired, by natural gas or oil.

The working fluid is pumped into the unit as liquid, passes sequentially through all the pressure-part heating surfaces where it is converted to steam as it absorbs heat, and leaves as steam at the desired temperature. There is no recirculation of water within the unit and, for this reason, a drum is not required to separate water from steam. The Universal-Pressure boiler may be designed to operate at either subcritical or supercritical pressures. The size of the unit is virtually unlimited.

Boiler Design

A boiler may be a unit complete in itself without auxiliary heat absorbing equipment, or it may constitute a rather small part of a large steam-generating complex, in which the steam is generated primarily in the furnace tubes, and the convection surface consists of a superheater, reheater, steaming economizer and air heater. In the latter case, it is possible to consider that a drum-type boiler comprises only the steam drum and the screen tubes between the furnace and the superheater. However, the furnace water-wall tubes, and usually a number of side-wall and support tubes in the convection portion of the unit, discharge steam into the drum and therefore effectively form a part of the boiler.

In the case of the Universal-Pressure boiler, there is no steam drum, but rather an arrangement of tubes in which steam is generated and superheated. Whether the boiler is a drum- or once-through type, whether it is an individual unit or a small part of a large complex, it is necessary in design to give proper consideration to the performance required from the total complex of the steam-generating unit. Within this framework, the important items that must be accomplished in boiler design are the following:

1. Determine the heat to be absorbed in the boiler and other heat transfer equipment, the optimum efficiency to use, and the type of fuel or fuels for which the unit is to be designed. When a particular fuel is selected, determine the amount of fuel required, the necessary or preferred preheated air temperature, and the quantities of air required and flue gas to be generated.
2. Determine the size and shape required for the furnace, giving consideration to location, the space requirements of burners or fuel bed, and incorporating sufficient furnace volume to accomplish complete combustion. Provision must also be made for proper handling of the ash contained in the fuel, and a water-cooled surface must be provided in the furnace walls to reduce the gas temperature leaving the furnace to the desired value.
3. The general disposition of convection heating surfaces must be so planned that the superheater and reheater, when provided, are located at the optimum temperature zone, where the gas temperature is high enough to afford good heat transfer from the gas to the steam, yet not so high as to result in excessive tube temperatures or excessive fouling from ash in the fuel.

While there is flexibility in the location of saturation or boiler surface, there must be enough total convection surface, either before or after the superheater, to transfer the heat required to heat the feedwater to saturation temperature and to generate the remainder of the steam required which is not generated in the furnace. This can be accomplished without an economizer, or an economizer can be provided to heat the feedwater to saturation temperature or even to generate up to 20% of the full-load steam requirement.

The foregoing must be accomplished in a design that provides for proper cleanliness of heating surfaces without buildup of slag or ash deposits and without corrosion of pressure parts.

4. Pressure parts must be designed in accordance with applicable codes using approved materials with stresses not exceeding those allowable at the temperatures experienced during operation.
5. A tight boiler setting or enclosure must be constructed around the furnace, boiler, superheater, reheater and air heater, and gas-tight flues or ducts must be provided to convey the gases of combustion to the stack.
6. Supports for pressure parts and setting must be designed with adequate consideration for expansion and local requirements, including wind and earthquake loading.

Combustion Data

The basis for the designer's selection of equipment includes factors involved in the selection of fuels. In most areas, there are several fuels available and their availability and cost may be expected to change during the lifetime of the plant, with the result that the unit must be designed to burn more than one fuel. It is usually possible to determine which fuel is the most difficult from the standpoint of combustion and ash handling, and the unit, therefore, is designed for the most difficult fuel that possibly may be used.

After the steam requirements — steam flow, steam pressure, and temperature — and boiler feedwater temperature are determined, the required rate of heat absorption, q, is determined from:

$$q = w'(h'_2 - h'_1) + w''(h''_2 - h''_1) \qquad (1)^*$$

where q = rate of heat absorption, Btu/hour
w' = primary steam of feedwater flow, pounds/hour
w'' = reheat steam flow, pounds/hour
h'_1 = enthalpy of feedwater entering, Btu/pound
h'_2 = enthalpy of primary steam leaving superheater, Btu/pound
h''_1 = enthalpy of steam entering reheater, Btu/pound
h''_2 = enthalpy of steam leaving reheater, Btu/pound

*1 Btu = 0.2520 Calorie
1 Btu/pound = 0.556 Calorie per kilogram

To determine unit efficiency, it is necessary to know the temperature of the flue gas leaving the unit. This temperature may be set at the point where further addition of heating surface to reduce gas temperature would not be justified by the increased economy obtained. In the case of sulfur-bearing fuels, flue gas temperature is usually kept above the dew point to avoid sulfur corrosion of economizer or air heater surfaces.

The efficiency of combustion is 100 minus the sum of the heat losses expressed in percent. For a fuel with known characteristics and a given flue gas temperature, heat losses are evaluated.

The fuel input rate is then determined from Eqs. (1) and (2):

$$w_F = q/(Q_H \times \text{eff}) \tag{2}$$

where w_F = fuel input rate, pounds/hour
Q_H = high heat value of fuel, Btu/pound
eff = efficiency

From the quantity of fuel to be burned per hour, the corresponding weight of air required and the weight of combustion gases produced are determined.

Furnace Design. When pulverized-coal or cyclone-furnace firing is used, the wall(s) in which the burners or cyclones are located must be designed to accommodate them and the necessary fuel- and air-supply lines. Minimum clearances, established by experience, must be maintained between burners to avoid interference of the fuel streams from the various burners with each other. Minimum clearances must also be provided between burners and side walls and between each burner and the opposite wall to avoid flame impingement on furnace walls with consequent possible overheating of wall tubes or excessive deposits of ash or slag.

Turbulence is primarily a function of the fuel-burning equipment, and its importance lies in supplying air, not only to individual fuel particles, but also to any unburned or partially burned gases until combustion is completed. The time factor is fulfilled primarily by providing sufficient furnace volume so that the combustion gases remain in the furnace long enough to assure complete combustion.

Water-Cooled Walls. Most modern boiler furnaces have all walls water-cooled. This not only reduces maintenance on the furnace walls, but also serves to reduce the gas temperature entering the convection bank to the point where slag deposit and superheater corrosion can be controlled by sootblowers.

Handling of Ash. In the case of coal and, to a lesser extent with oil, a very important factor is the presence of ash in the fuel. If the ash is not properly considered in the design and operation, it can and does deposit not only on furnace walls and floor, but through the convection banks. This not only reduces the heat absorbed by the unit, but also increases draft loss, corrodes pressure parts, and eventually can cause shutdown of the unit for cleaning and repairs. There are two approaches to the handling of ash: (1) dry-ash furnace; and (2) slag-tap furnace.

In the dry-ash furnace, particularly applicable to coals with high ash and fusion temperatures, the furnace is provided with a hopper bottom and with sufficient cooling surface, so that the ash impinging on the furnace walls or hopper bottom is solid and dry and can be removed essentially as dry particles. When pulverized coal is burned in a dry-ash furnace, about 80% of the ash is carried through the convection banks; most of the fly ash is normally removed by particulate-removal equipment located just ahead of the stack.

With many coals having low ash fusion temperatures, it is difficult to utilize a dry-bottom furnace because the slag is either molten or sticky and tends to cling and build up on the furnace walls and bottom. The slag-type furnace has been developed to handle coals of these types. The most successful form of the slag-tap furnace is that used in conjunction with cyclone-furnace firing. The furnace comprises a two-stage arrangement. In the lower part of the furnace, gas temperature is maintained high enough so that the slag drops in liquid form onto a floor where a pool of liquid slag is maintained and tapped into a slag tank containing water. In the upper part of the furnace, gases are cooled below the ash fusion point so that ash carried over into the convection banks is dry and does not adhere.

Convection Boiler Surface

The gas temperature leaving the furnace or entering the boiler depends mainly on the ratio of heat released to amount of furnace-wall cooling surface installed. Because the cost of furnace-wall cooling surface is relatively higher than that of boiler surface, the furnace size and surface are limited to the amount required to lower the gas temperature entering the convection tube banks sufficiently to avoid ash deposits.

The first few rows of tubes in the convection bank may be boiler tubes widely spaced to provide gas lanes wide enough to prevent plugging with ash and slag and to facilitate cleaning. These widely spaced boiler tubes are known as the slag screen or boiler screen. In many large units, they are used to support the furnace rear wall tubes. These screen tubes receive heat by radiation from the furnace, and by radiation and convection from the combustion gases passing through them.

In large contemporary units, the superheater generally replaces the boiler screen or, if not, is located immediately beyond it.

Design of boiler surface after the superheater will depend on the particular type of unit selected, desired gas temperature drop, and acceptable gas pressure drop (draft loss) through the boiler surface. Typical arrangements of boiler surface for various types of boilers have been illustrated. The object in the design of convection heating surfaces is to establish the combination of tube diameter, tube spacing, length of tubes, number of tubes wide and deep, and gas baffling that will give the desired gas temperature drop with the pressure drop permissible.

Heating surface and pressure drop are directly interrelated since both are primarily dependent on gas mass velocity. If either heating surface or pressure drop is increased, the other must decrease in order to maintain the desired gas temperature drop (heat transfer). Hence there is an optimum gas mass velocity which results in the optimum combination of heating surface and gas pressure drop.

For a given gas mass velocity (pounds of gas per hour per square foot of gas flow channel) or for a given gas velocity, a considerably higher gas film conductance, heat absorption, and draft loss result when the gases flow at right angles to the tubes (crossflow) than when they flow parallel to the tubes (longitudinal flow). Gas turns between tube banks generally add draft loss with little or no benefit to heat absorption and should be designed for easy flow.

From a long record of experience, given sets of conditions for each fuel to be burned have been effectively established as the conditions of economic practice. While these conditions vary as improvements occur over a period of years, at any particular time competitive economies acts to hold most of the variables involved within a fairly limited range.

Superheaters and Reheaters

Early in the eighteenth century, it was shown that substantial savings in fuel could be experienced when steam engines were run with some superheat in the steam. In the late 1800s, lubrication problems were encountered with reciprocating engines, but once these were overcome, development of superheaters continued.

Commercial development of the steam turbine hastened the general use of superheat. By 1920, steam temperatures of 343 °C, representing superheats of 140 °C were generally accepted. In the early 1920s, the regenerative cycle, using steam bled from turbines for feedwater heating, was developed to improve station economy without going to higher steam temperatures. At the same time, superheater development permitted raising the steam temperature to 385 °C. A further gain in economy by still higher temperature was at that time limited by allowable superheater tube-metal temperature. This led to the commercial use of reheat, where the steam leaving the high-pressure stage of the turbine was reheated in a separate reheat superheater and returned at higher temperature and enthalpy to the low-pressure stage.

The first reheat unit for a central station was proposed in 1922 and went into service in 1924. It was designed for 650 psi (42 atmospheres) and operated at 550 psi and 385 °C. Exhaust steam from the high-pressure turbine was reheated to 385 °C at 135 psi (9.2 atmospheres).

Advantages of Superheat and Reheat. When saturated steam is utilized in a steam turbine, the work done results in a loss of energy by the steam and consequent condensation of a portion of the steam, even though there is a drop in pressure. The amount of work that can be done by the turbine is limited by the amount of moisture which can be handled by the turbine without excessive wear on the turbine blades. This is normally somewhere between 10 and 15% moisture. It is possible to increase the amount of work done by moisture separation between turbine stages, but this is economical only in special cases. Even with moisture separation, the total energy that can be transformed to work in the turbine is small compared with the amount of heat required to raise the water from

feedwater temperature to saturation and then evaporate it. Thus, moisture constitutes the basic limitation in turbine design.

Because a turbine generally transforms the heat of superheat into work without forming moisture, the heat of superheat is essentially all recoverable in the turbine. This is illustrated in the temperature-entropy diagram of the ideal Rankine cycle, where the heat added to the right of the saturated vapor line is shown as 100% recoverable. While this is not always entirely correct, the Rankine cycle diagrams of Fig. 11 indicate that this is essentially true in practical cycles.

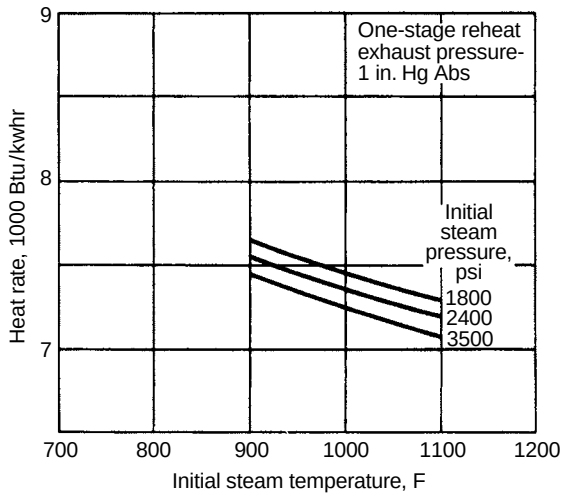

Fig. 11. Effects of changes in steam temperature and pressure on performance of ideal Rankine cycle with one-stage reheat.

The foregoing factors, however, are not specifically applicable at steam pressures in the vicinity of the critical point. The term *superheat* is not quite appropriate in defining the temperature of the working fluid at or above the critical point. However, even at pressures exceeding 3208 psi (∼218 atmospheres), heat added at temperatures above 374 °C, is essentially all recoverable in a turbine.

Types of Superheaters. The original and somewhat basic type of superheater and reheater was the convection unit for gas temperatures where heat transfer by radiation was very small. With a unit of this type, steam temperature leaving the superheater increases with boiler output because of the decreasing percentage of heat input that is absorbed in the furnace, leaving more heat available for superheater absorption. Since convection heat transfer rates are almost a direct function of output, the total absorption in the superheater per pound of steam increases with increase in boiler output. See Fig. 12. This effect is increasingly pronounced the farther the superheater is removed from the furnace, that is, the lower the gas temperature entering the superheater.

Conversely, the radiant superheater receives its heat through radiation and practically none from convection. Because the heat absorption of furnace surfaces does not increase in direct proportion to boiler output, but at a considerably lesser rate, the curve of radiant superheat as a function of load slopes downward with increase in boiler output. In certain cases, the two opposite-sloping curves have been coordinated by the combination of radiant and convection superheaters to give flat superheat curves over a wide range in load as typically indicated in Fig. 12. A separately fired superheater has the characteristic that it can be fired to produce a flat superheater curve.

The early convection superheaters were placed above or behind a deep bank of boiler tubes in order to shield them from the fire or from the higher temperature gases. The greater heat absorption required in the superheater for higher steam temperatures made it necessary to move the superheater closer to the fire. This new location brought with it problems which were not apparent with the superheaters located in the original lower-gas-temperature zone. Steam- and gas-distribution difficulties and instances of general overheating of tube metal were ultimately resolved by improved superheater design, including higher mass velocity of the steam. This increased the heat conductance through the steam film, resulting in lower tube-metal temperatures, and also improved steam distribution by increasing pressure drop through the tubes.

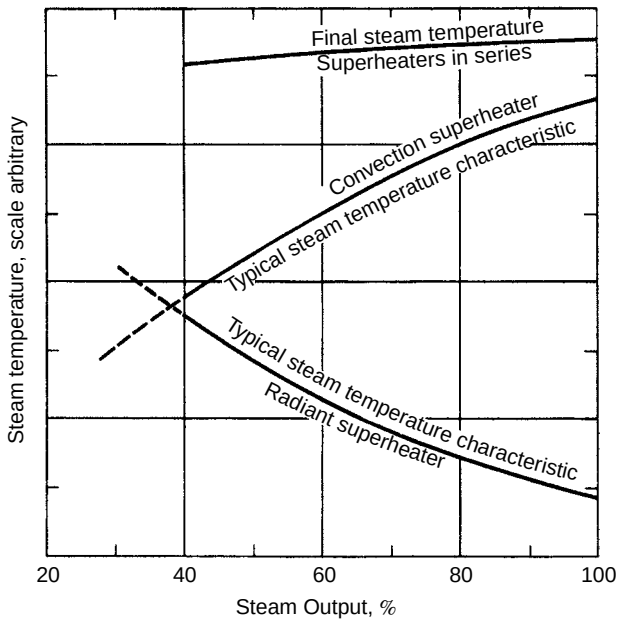

Fig. 12. A substantially uniform final steam temperature over a range of output can be attained by a series of arrangements of radiant and convection superheater components.

Steam mass velocity in contemporary superheaters ranges from as low as 100,000 to 1,000,000 pounds per square foot (488,200 to 4,882,000 kilograms per square meter) per hour or higher, depending upon pressure, steam and gas temperatures, and the tolerable pressure drop in the superheater. The fundamental considerations governing superheater design apply also to reheater design. However, the pressure drop in reheaters is critical because the gain in heat rate with the reheat cycle can be fully nullified by too much pressure drop through the reheater system. Hence, steam mass flows are generally somewhat lower in the reheater.

Steam-Temperature Adjustment and Control

Improvement in the heat rate of the modern boiler unit and turbine results in large part from the high cycle efficiency possible with high steam temperatures. The importance of regulating steam temperature within narrow limits is evident from Fig. 11, which shows that a change of ∼20 °C corresponds to a change of about 1% in heat rate at pressures from 1800 to 3500 psi (122 to 238 atmospheres).

Other important reasons for accurate regulation of steam temperature are to prevent failures from overheating parts of the superheater, reheater, or turbine, to prevent thermal expansion from reducing turbine clearances to the danger point, and to avoid erosion from excessive moisture in the last stages of the turbine. The control of fluctuations in temperature from uncertainties of operation, such as slag or ash accumulation is important. However, superheat and reheat steam temperatures in steam generation are mainly affected by variations in steam output. See Fig. 12.

With drum-type boilers, steam output and pressure are maintained constant by firing rate, while the resulting superheat and reheat steam temperatures depend on basic design and other important operating variables, such as: the ratio of convection to radiant heat-absorbing surface, excess air, feedwater temperature, changes in fuel that affect turbine characteristics and ash deposits on the heating surfaces, and the specific burner combinations in service. In the Universal-Pressure, once-through boiler which has a variable transition zone, steam output and pressure are controlled by the boiler feed pump and steam temperature by the firing rate, leaving reheat steam temperature as a dependent variable. Standard performance practice for steam generating equipment permits a tolerance of plus or minus 5.5 °C in a specified steam temperature.

Fossil Fuel Power Plant Research

There were two crises that commenced during the 1970s and that had not been fully resolved as of the late 1990s. These were the need to conserve energy and during the energy crisis to conserve petroleum

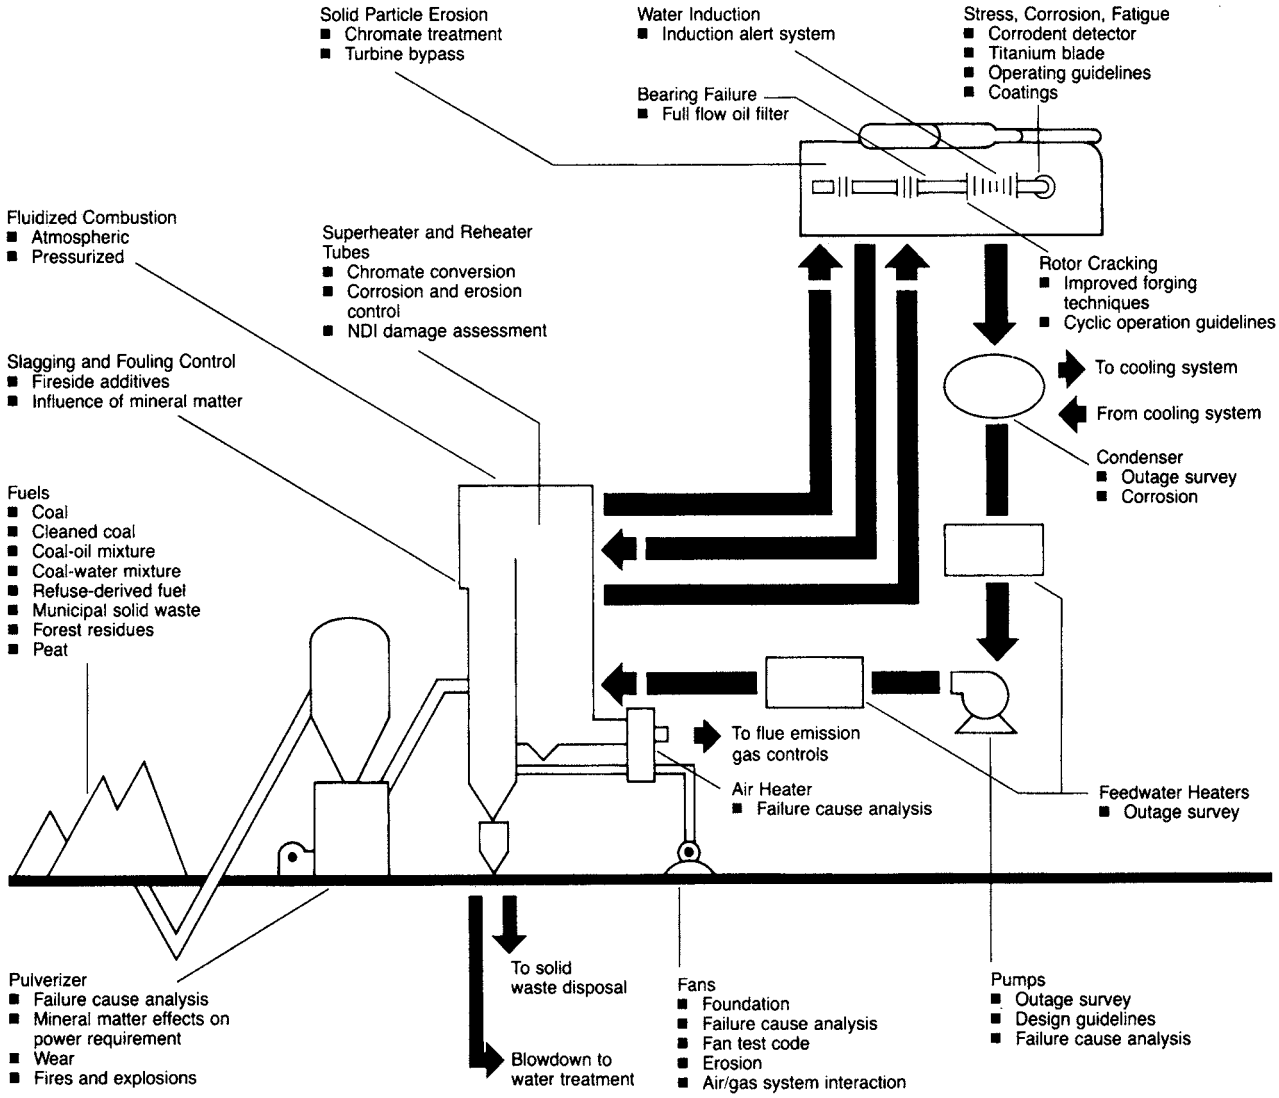

Fig. 13. Diagrammatic summary of the kinds of problems encountered in steam and electric power generation that continue to be addressed by researchers. (*EPRI, Electric Power Research Institute, Palo Alto, California.*)

and natural gas in particular — and the need to greatly reduce power emissions. Thus, much continuing research has been directed toward solving these problems expeditiously, yet economically. While, as of the late 1990s, the energy problem has lessened, many authorities agree that the cost of energy will continue to remain high. Energy conservation has had a major impact on higher steam and power generating efficiencies. Exemplary of these research efforts are the programs of the Electric Power Research Institute (Palo Alto, California). A pictorial representation of the power plant areas which have been under intensive study is given in Fig. 13.

BOILING. If a liquid is heated at constant pressure in an inert atmosphere, evaporation takes place at the free surface, but bubbles may form in the interior of the liquid. This process is also known as *ebullition*. The vapor pressure inside a bubble of small diameter is considerably less than the vapor pressure over a plane surface, so that bubbles cannot persist below the temperature at which the vapor pressure equals the external pressure and do not appear until the local temperature is rather greater than this. If the whole of the liquid is above the critical temperature, usually called the "boiling-point," introduction of a source of bubbles, either deliberate or accidental, causes rapid ebullition until evaporation reduces the temperature. A strong source of heat may cause the superheating necessary for ebullition in a thin layer. The bubbles formed in the layer grow until they rise out of it and the "boiling heat-transfer" associated with the transient occurrence of bubbles either in the liquid or attached to the heated surface leads to some curious effects. Typically, normal single phase convection is succeeded by nucleate boiling in which bubbles form on nuclei on the surface and heat transfer is much increased. Further rise of wall temperature causes partial formation of a film and a rapid decrease of heat transfer as film boiling is established.

In modern boilers,* as much as 1 to 3 cubic feet of steam per minute may be formed in a 5-foot length of $2\frac{1}{2}$-inch tubing in the furnace area. Water must be continuously supplied for this steam generation and, in many designs, excess water is provided to protect the tubes from overheating. In order to obtain information on the nature of boiling, a number of investigators have experimented with electrically heated wires in a pool of water. Other investigators have performed the experiment of heating a tube or other type of flow channel cooled by a flow of water at a pressure below critical, and subjecting the tube to various levels of heat input.

Figure 1 is a generalized curve summarizing the results of these investigations. This curve can be regarded as a general correlation of test results at a number of different heat inputs to heated wires in a pool of water or to heated tubes or flow channels. It can also be regarded as a series of different heat inputs to a single flow channel. In this case, the points on the curve represent a series of temperature differences (surface temperature minus bulk water or steam temperature) corresponding to the water and steam conditions existing at a single location on the flow channel for different levels of heat flux or heat input. If the channel is evenly heated along its length, the location represented is the outlet end of the heated section of the channel. Absolute values on the curve are dependent on many factors, including pressure, flow-channel geometry, mass velocity, flux patterns, and degree of water subcooling.

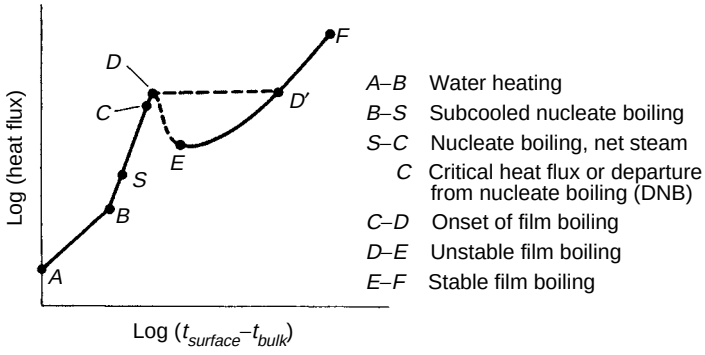

Fig. 1. Heat transfer to water and steam in a heat flow channel. Relation of heat flux to temperature difference between channel-wall and bulk-water or steam temperature.

For all heat input conditions (points on the figure), water pressure and temperature at the inlet to the channel remain constant. Hence, the amount of subcooling (saturation temperature minus water temperature) at the inlet also remains constant. Ideally, water flow through the tube is maintained at a fixed rate.

The initial heat flux at point *A* is shown increasing on a logarithmic scale for points to the right of *A*. Until point *B* is reached, the heat input is not sufficient to produce boiling.

At *B*, the local heat flux is sufficient to raise the water temperature adjacent to the heated surface to saturation temperature, or slightly above, and a change from the liquid to the vapor state occurs locally. This change is characterized by the coexistence of both phases at essentially the same temperature locally, differing only in a few degrees of liquid superheat necessary for heat transfer and by heat absorption required to overcome the molecular binding forces of the liquid phase. Here, the change of state is accompanied by ebullition of the vapor as opposed to evaporation at a free surface and the term boiling is used to describe the process. Also, the ebullition takes place at an interface other than that of the liquid and its vapor, actually at a solid-liquid interface; hence the boiling is described as "nucleate boiling."

The bulk of the water does not reach saturation temperature until the heat flux of point *S* is reached. Between *B* and *S*, the steam bubbles formed at the heated surface condense quickly in the main stream, giving up their latent heat to raise the temperature of the water. This condition is known as subcooled-nucleate or local boiling. Nucleate boiling occurs at all points up to *C*; beyond *S*, the bubbles do not collapse, since this part of the curve represents boiling with the water bulk temperature at saturation.

Both nucleate-boiling regimes, subcooled and saturated, are characterized by very high heat transfer coefficients. These are ascribed to the high secondary velocities of water caused by the liberation of surface tension energies available in the liquid-vapor-solid interfaces at the instant of bubble release from the heating surface. This is a convection-type transfer coefficient based on bubble kinetics and is also affected to some extent by bulk mass velocity, depending on the velocity range. As the result of these high heat transfer coefficients, tube- or flow-channel surface temperatures do not greatly exceed the saturation temperature.

Beyond the nucleate boiling region ($B - C$ in the figure), the bubbles of steam forming on the hot tube surface begin to interfere with the flow of water to the surface and eventually coalesce to form a film of superheated steam over part or all of the heating surface. This condition is known as "film boiling." From *D* to *E* film boiling is unstable; beyond point *E* film boiling becomes stable.

In a fossil-fuel-fired boiler or in a nuclear reactor, when the local heat flux exceeds that corresponding to point *D*, the surface temperature may rise very quickly, along the horizontal dotted line in the figure, to point D'. If the temperature at D' is sufficiently high, the heating surface burns out or melts. Hence, *D* is known as the burnout point and *C*, which may be very close to it, as the point of departure from nucleate boiling (DNB), or the critical heat flux.

Stable and even unstable film boiling is acceptable in certain types of heat transfer equipment where the temperature of the heat source is within the safe operating range of the equipment, or where the boiling film heat transfer coefficient is the controlling resistance to heat flux. Steam generators for pressurized-water reactor (nuclear) systems, which are actually water-to-boiling water heat exchangers, and certain types of process heat exchange equipment are in this category.

BOILING-ALLEROD. See **Climate**.

BOILING CURVE AND CONDENSATION CURVE. Consider the phase diagram (Fig. 1) of a binary system forming a liquid and a vapor phase at constant pressure. Curve I is the boiling curve, which gives the coexistence temperature as a function of liquid composition; and curve II is the condensation curve, which gives the coexistent temperature as a function of the composition of the vapor phase. If the temperature is increased, vaporization begins when the boiling curve is crossed. Inversely, condensation begins when the temperature is decreased below the condensation curve.

BOILING POINT. The temperature at which the equilibrium vapor pressure between a liquid and its vapor is equal to the external pressure on the liquid. Physically, boiling (or ebullition) cannot begin in a liquid until the temperature is raised to such a point that incipient bubbles forming within the liquid can grow rather than collapse. But for a bubble to grow, its internal vapor pressure must exceed the hydrostatic pressure exerted on the bubble interface. For liquids heated in containers that are open and fairly

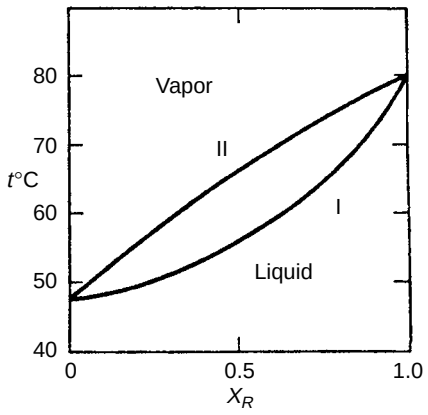

Fig. 1. Temperature composition of a liquid-vapor system at constant pressure.

shallow, this hydrostatic pressure is essentially the same as the external atmospheric pressure, so ebullition begins when the equilibrium vapor pressure equals atmospheric pressure. In liquids perfectly free from foreign particles and contained in a vessel with perfectly smooth walls, boiling will not begin even at the above-described temperature, for boiling resembles condensation in that "nuclei" must exist to initiate the process. When a very pure liquid sample has been heated above its nominal boiling point it is said to have been superheated, a state that is very similar to the state of supersaturation in which a vapor may exist in a nucleus-free environment. Because of the normal decrease of barometric pressure with height, the nominal boiling point of water decreases 3.0°–3.5 °C (37°–38 °F) for each kilometer increase of altitude. See also **Hypsometer**. The boiling point is a colligative property of a solution; with an increase in dissolved matter, there occurs a raising of the boiling point. The boiling point of pure water at standard pressure is equal to 100 °C (212 °F) and is a fiducial point for thermometer calibration.

AMS

BOILING POINT CONSTANT. Consider a dilute solution in which all solute species may be regarded as nonvolatile. The vapor in equilibrium with the solution is then formed from the solvent only. Call T^0 the boiling point of the pure solvent at the pressure concerned, and T the boiling point of the solution. For a dilute solution, the difference

$$\theta = T - T^0$$

will be small compared with T^0.

If the solution is also ideal, one has

$$\theta = \frac{R(T^0)^2}{\Delta_e h^0} \frac{M_1}{1000} \sum_s m_s = \theta_e \sum_s m_s$$

M_1 is the molar mass of the solvent, $\Delta_e h^0$ its latent heat of vaporization in kcal per mole at temperature T^0, m_s the molality of solute s; θ_e is called the *boiling point constant*, or *ebullioscopic constant*. It depends only on the properties of the solvent. For water,

$$\theta_e = 0.51\,^\circ\mathrm{C}$$

Boiling Point Elevation

The boiling point of a solution is, in general, higher than that of pure solvent, and the elevation is proportional to the active mass of the solute for dilute (ideal) solutions.

$$\Delta T = Km$$

where ΔT is the elevation of the boiling point, K is the *boiling point constant* or the *ebullioscopic constant* and m, the molality of the solution.

BOILING POINT ELEVATION. The boiling point of a solution is, in general, higher than that of pure solvent, and the elevation is proportional to the active mass of the solute for dilute (ideal) solutions.

$$\Delta T = Km$$

where ΔT is the elevation of the boiling point, K is the *boiling point constant* or the *ebullioscopic constant* and m, the molality of the solution.

There are several methods for measuring elevation: In the Beckmann method a Beckmann-type thermometer is immersed in a weighed amount of solvent and the boiling point determined by gentle heating until a steady temperature is reached. A weighed amount of solute is then added and the boiling point redetermined. The difference gives the elevation of the boiling point. The glass vessel containing the liquid is provided with a platinum wire sealed through the bottom to promote steady boiling and to prevent overheating, and reflux condensers are used to minimize loss of liquid.

In the Landsberger method, vapor from boiling solvent is passed through the solvent contained in another vessel and by giving up its latent heat will eventually raise the liquid to the boiling point. At this stage a weighed amount of solute is added to the second vessel and the boiling point is again determined.

In the Cottrell method, the thermometer is placed in the vapor phase above the surface of the liquid and the apparatus so designed that boiling liquid is pumped continuously over the bulb of the thermometer.

BOILING POINT REACTOR. See **Nuclear Power Technology**.

BOILS. A localized purulent infection of the skin and underlying tissues taking the form of nodules which initially are hard, but progress to a softer stage, ultimately rupturing and draining. Relatively small abscesses sometimes are termed furuncles. The term *carbuncle* often is used to describe larger boils, particularly those with multiple openings. Boils may occur singly or in multiples and, in some cases, may be chronic and recurrent over long periods until the underlying causes are found and corrected. The immediate cause is attributed to staphylococci, although streptococci also may be present.

BOISE DE ROSE. An essential oil obtained from evergreen trees of the *Lauraceae* family, notably *Aniba rosaeodora* Ducke, and *Ocotea caudata* Mer., which are found growing wild in the forests of the Amazon basin (Brazil and Peru). The chopped bark of the trees is steam-distilled to yield a colorless to pale yellow oil. Depending upon variety of tree used, the oil has a sweet, slightly wood characteristic odor in which camphoraceous notes are readily detected. The main constituent of the oil is linalool. Boise de rose oil finds extensive use in perfumery, particularly in soap and cosmetics. The oil is also used as a flavoring in chewing gum, baked goods, ice cream, candy, and beverages.

BOLE. A fine-grained, sticky, bright red laterite; the decomposition product of basic igneous rocks, such as basalt.

BOLIDE. A term occasionally applied to meteors that are observed to explode in the air and break up into two or more fragments. Such objects are frequently described as having the appearance of an exploding rocket. Not infrequently following the explosion of a bolide is heard a sharp detonation. See also **Fireball**.

BOLL WEEVIL *(Insecta, Coleoptera).* A snout-beetle or weevil, *Anthonomous grandis*, averaging about $\frac{1}{4}$ inch (6 millimeters) in length, which damages cotton. The adult punctures the cotton squares to lay its eggs and thus prevents the formation of the boll, and later in the season deposits eggs in the bolls, where its larvae damage the seeds and lint.

The species entered the United States from Mexico in the early 1890s and is now an established pest in practically all cotton-growing areas, causing an annual loss in the many millions of dollars. The problem is met by various methods of keeping the insect in check. The destruction of cotton plants after the crop is harvested kills many insects, and spraying the growing plants with control chemicals has been found effective.

BOLLWORM *(Insecta, Lepidoptera).* The pink cotton bollworm is a small moth whose larva, the bollworm proper, lives in the flowers of cotton and usually prevents their maturing, and later enters the bolls and damages the seed and lint. The species lives on several other species of plants and is therefore difficult to check, although it is not yet as serious a pest as the boll weevil. The larva of another moth of larger size, more widely known as the corn earworm, also attacks cotton squares and bolls, as well as corn and tobacco, and so is known as the cotton bollworm. It is estimated to cause several millions of dollars' damage each year. Fall plowing and disking are practiced to destroy this insect in the pupal stage, which is passed in the ground, and dusting as for the weevil is effective.

Entomological Society of America http://www.entsoc.org

BOLOMETER. An instrument for measuring radiant energy by measuring changes in resistance of a temperature-sensitive device exposed to radiation. For example, the heating effect of an unknown quantity of radio-frequency power may be compared with that of a measured amount. The bolometer generally is incorporated into a bridge network. The technique generally is applicable to measurement of low levels of RF power below 100 milliwatts. Also called *actinic balance*.

In meteorological applications, two identical, blackened, thermally sensitive electrical resistors are used in a Wheatstone bridge circuit. Radiation is allowed to fall on one of the elements, causing a change in its resistance. The change is a measure of the intensity of the radiation.

BOLSON. An undrained basin in an arid region, which generally is partly filled with rock-waste washed by temporary streams from the bordering mountains.

BOLTZMANN, LUDWIG (1844–1906). Boltzmann was born in Vienna. He was a great theoretical physicist and is known for his contributions to mathematical analyses of physical phenomena, and to the kinetic theory of gases, especially in regard to viscosity and diffusion.

Unique to Boltzmann is the H-theorem that resolves the problem of microscopic reversibility and macroscopic irreversibility. He is recognized for the Maxwell-Boltzmann integro differential equation governing the change in distribution of atoms due to collisions. Throughout his life, Boltzmann used his intuition and this intuition led him to consider the probability of energy distributions in gases. He believed that thermodynamic phenomena were the macroscopic reflection of atomic phenomena regulated by mechanical laws and by chance. He was ridiculed for his idea, and this ridicule may have led to his depression and suicide. We now acknowledge Boltzmann as the creator of statistical mechanics.

See also **Boltzmann's Distribution Law**; and **Boltzmann Transport Equation**.

J. M. I.

BOLTZMANN'S CONSTANT. (Sometimes called *gas constant per molecule, Boltzmann's universal conversion factor*.) The ratio of the universal gas constant to Avogadro's number; equal to 1.3804×10^{23} W K^{-1}.

BOLTZMANN'S DISTRIBUTION LAW. Consider a system composed of molecules, of one or more kinds, able to exchange energy at collisions but otherwise independent of one another. Evidently we cannot say anything useful or interesting about the state of a particular molecule at a particular time. We can however make useful statements about the average fraction of molecules of a given kind in a given state, or, what is the same thing, the fraction of time spent by each molecule of a given kind in a given state. If the system is maintained at a definite temperature, then the fraction of molecules of a given kind in a given state is determined by the energy of this state and by the temperature.

In particular if we denote by i and k two completely defined states of a molecule of a given kind and by E_i and E_k the energies of these two states then the average numbers N_i and N_k of molecules in these two states are related by

$$N_i/N_k = \exp\{-\beta(E_i - E_k)\} \tag{1}$$

where β is a parameter having a positive value determined entirely by the thermostat; i.e., β has the same value for all states of a given kind of molecule and for all kinds of molecules. In other words β has all the characteristics of temperature except that it decreases as temperature increases. If we write

$$\beta = 1/kT \tag{2}$$

then it can be shown that T is identical with thermodynamic (or absolute) temperature and k is a universal constant whose value determines the unit of T called the degree. When k is given the value 1.38041×10^{-23} joule/degree, the temperature scale becomes the Kelvin scale defined by $T = 273.16$ K at the triple point of water. Substitution of Eq. (2) into Eq. (1) leads to

$$N_i/N_k = \exp\{-(E_i - E_k)/kT\} \tag{3}$$

This fundamental relation is called Boltzmann's distribution law after the creator of statistical mechanics, Ludwig Boltzmann (1844–1906), Professor of Physics in Leipzig, and k is called Boltzmann's constant.

We must now discuss the meaning of the words used above, "completely defined state." These words have one meaning in classical mechanics and a different, but related, meaning in quantum mechanics. Since the quantum definition is the simpler we shall discuss it first. We begin by considering a system of highly abstract "molecules" having only a single degree of freedom, for example linear oscillators. The quantum states form a simple series specified by consecutive integers called the quantum numbers. In this simple example there is no ambiguity in the meaning of "completely defined state"; each state i is completely defined by the integral value of a single quantum number. Let us now consider a "molecule" with three degrees of freedom such as a structureless particle moving in three-dimensional space. The complete specification of this particle's state requires not one but three integral quantum numbers. If the particle moves freely in a cubical box, the three quantum numbers may be associated with motion along the three directions normal to the faces of the box. The subscript labels i and k in the previous formulas are abbreviations for sets of three quantum numbers. For example i might mean (2, 5, 1) and k might mean (3, 4, 2). There can now be several states having the same energy. For a particle moving freely in a cubical box, it follows from symmetry that the states (2, 5, 1), (1, 2, 5), (5, 1, 2), (1, 5, 2), (2, 1, 5), and (5, 2, 1) all have the same energy; such an energy level is called sixfold degenerate. (One should *not* speak of a p-fold degenerate *state*, but of a p-fold degenerate energy level.) It is sometimes desirable to consider the fraction of molecules having a given energy rather than the fraction in a given state. If N_r and N_s denote the average number of molecules of a given kind having energy E_r and E_s then evidently

$$N_r/N_s = (p_r/p_s)\exp\{-(E_r - E_s)/kT\} \tag{4}$$

Alternatively, if f_r denotes the average fraction of molecules of a given kind having energy E_r, then

$$f_r = p_r \exp(-E_r/kT)/\sum_s p_s \exp(-E_s/kT) \tag{5}$$

The sum $\sum_s$ occurring in the denominator is called the partition function.

It may happen that certain degrees of freedom are completely independent of other degrees of freedom. We call such degrees of freedom "separable." The partition function can then be separated into factors relating to the several sets of separable degrees of freedom, and Boltzmann's distribution law is applicable separately to each set of separable degrees of freedom. For example, for an electron moving freely in a rectangular box, the translational motions normal to the three pairs of faces and the fourth degree of freedom due to spin are all separable.

We shall now consider briefly the meaning of completely specified state according to classical mechanics. We know that classical mechanics is merely an approximation, sometimes good but sometimes bad, to quantum mechanics. Motion in each separable degree of freedom can be described classically by a coordinate x and its conjugate momentum p_x. If x and p_x are plotted as Cartesian coordinates, the diagram is called the phase plane. There is a simple correlation between the quantum definition and the classical descriptions: the density of quantum states is one per area h (Planck's constant) in the phase plane. This may be extended to several degrees of freedom. If there are f degrees of freedom, the motion is described by f coordinates $q_1, \ldots q_f$ are the conjugate momenta $p_1, \ldots p_f$. We can imagine these plotted in a $2f$ dimensional Cartesian space called phase space. There is then one quantum state per $2f$ dimensional volumes h^f of phase space. In the classical as in the quantum description there can be degenerate energy values and there can be separable degrees of freedom. The classical description is a good approximation to the quantum description when the spacing between energy levels is small compared with kT. An example of an effectively classical separable degree of freedom is the motion in a given direction of a free particle. If the linear coordinate is denoted by x and the linear momentum by p_x, then the fraction of molecules at a position between x and $x + dx$ and having a momentum between p_x and $p_x + dp_x$ is

$$\frac{\exp(-{p_x}^2/2mkT)dx\,dp_x}{\int dx \int_{-\infty}^{\infty} dp_x \exp(-{p_x}^2/2mkT)} \tag{6}$$

where m is the mass of the particle so that its (kinetic) energy is ${p_x}^2 p/2m$. In the classical treatment, the kinetic and potential factors are separable. Consequently the fraction of molecules, anywhere or everywhere, having momentum between p_x and $p_x + dp_x$ is

$$\exp(-{p_x}^2/2mkT)dp_x / \int_{-\infty}^{+\infty} \exp(-{p_x}^2/2mkT)dp_x \tag{7}$$

Equation (7) is called Maxwell's distribution law after Clerk Maxwell (1831–79), Professor of Physics at Cambridge (England), who obtained it in 1860, before Boltzmann in 1871 obtained his wider distribution law. Maxwell derived his distribution law from the conservation of energy together with the assumption that the motion is separable in three mutually orthogonal directions. The latter assumption was violently attacked by mathematicians, but we now recognize that the assumption is both reasonable and true.

In conclusion we must mention that a necessary condition for the validity of Eq. (3), and consequently of other formulas derived from Eq. (3) is that $N_i \ll 1$ for the state (or states) of lowest energy and *a fortiori* for all other states. When this inequality does not hold, Boltzmann's distribution law must be replaced by a more general and more precise distribution law, either that of Fermi and Dirac or that of Bose and Einstein according to the nature of the molecules. See also **Statistical Mechanics**.

BOLTZMANN TRANSPORT EQUATION. The fundamental equation describing the conservation of particles which are diffusing in a scattering, absorbing, and multiplying medium. It states that the time rate of change of particle density is equal to the rate of production, minus the rate of leakage and the rate of absorption, in the form of a partial differential equation such as

$$\frac{\partial n}{\partial t} = \text{production} - \text{leakage} - \text{absorption}$$
$$= S + D\nabla^2\phi + \phi \sum_a$$

in which S in the cgs system is in units of neutrons cm^{-3} sec^{-1}, D is the diffusion coefficient in units of cm, $\phi = nv$ is the neutron fluence in units of neutrons cm^{-2} sec^{-1}, $\sum_a$ is the absorption cross section per unit volume in units of cm^{-1}, and ∇ is del, the vector differential operator.

BOLUS. A mass of masticated food within the mouth or alimentary canal.

BOMBARDIER BEETLE *(Insecta, Coleoptera).* A ground-beetle which discharges a strong-smelling volatile secretion in small jets when disturbed. Each discharge is accomplished by an audible report and a visible puff of vapor as the secretion evaporates. The material ejected contains benzoquinone and 2-methylbenzoquinone. The numerous species make up the genus *Brachinus*.

BOMBARDMENT. This term is used in atomic and nuclear physics to denote the action of directing a stream of particles or photons against a target. The term is sometimes used for irradiation in a nuclear reactor.

BOND ALBEDO. The ratio of the amount of light reflected from a sphere exposed to parallel light to the amount of light incident upon it. Sometimes shortened to *albedo*. The Bond albedo is used in planetary astronomy.

BOND CALORIMETER. See **Calorimetry**.

BOND (Chemical). An attractive force between atoms strong enough to permit the combined aggregate to function as a unit. A more exact definition is not possible because attractive forces ranging upward from 0 to those involving more than 250 kcal/ mole of bonds are known. A practical lower limit may be taken as 2-3 kcal/mole of bonds, the work necessary to break approximately 1.5×10^{24} bonds by separating their component atoms to infinite distance.

All bonds appear to originate with the electrostatic charges on electrons and atomic nuclei. Bonds result when the net coulombic interactions are sufficiently attractive. Different principal types of bonds recognized include metallic, covalent, ionic, and bridge.

Metallic bonding is the attraction of all the atomic nuclei in a crystal for the outer shell electrons that are shared in a delocalized manner among all available orbitals. Metal atoms characteristically provide more orbital vacancies than electrons for sharing with other atoms.

Covalent bonding results most commonly when electrons are shared by two atomic nuclei. Here the bonding electrons are relatively localized in the region of the two nuclei, although frequently a degree of delocalization occurs when the shared electrons have a choice of orbitals. The conventional *single* covalent bond involves the sharing of two electrons. There may also be *double* bonds with four shared electrons, *triple* bonds with six shared electrons, and bonds of intermediate multiplicity.

Covalent bonds may range from *nonpolar*, involving electrons evenly shared by the two atoms, to extremely *polar*, where the bonding electrons are very unevenly shared. The limit of uneven sharing occurs when the bonding electron spends full time with one of the atoms, making the atom into a negative ion and leaving the other atom in the form of a positive ion. Ionic bonding is the electrostatic attraction between oppositely charged ions.

Bridge bonds involve compounds of hydrogen in which the hydrogen bears either a + or − charge. When hydrogen is attached by a polar covalent bond to one molecule, it may attract another molecule, bridging the two molecules together. If the hydrogen is +, it may attract an electron pair of the other molecule. This is called a *protonic bridge*. If the hydrogen is −, it may attract through a vacant orbital the nucleus of an atom of a second molecule. This is called a *hydridic bridge*. Such bridges are at the lower range of bond strength but may have a significant effect on the physical properties of condensed states of those substances in which they are possible.

See also **Chemical Elements**.

BONE. The hard, calcified tissue that forms the major part of the skeletal system of the body. The bones and cartilage are referred to as *connective* or *supporting* tissue because their chief function is structural. The distinction should be made between the terms *bone* and *bones*. Bone is a *tissue*, derived from connective tissue cells that become specialized in function. Bones are *organs*, such as the skull, pubis, tibia, fibula, and so on. The principal bones of the human body are diagrammed in the article on **Skeletal System**.

Bone tissue consists of two permanent components: (1) the specialized cells of the bone; and (2) the surrounding *matrix*, which is composed of minute fibers and a cementing substance. This cementing substance contains mineral salts, mainly calcium phosphate. Similar to bone, and comprising a portion of the skeleton is *cartilage*. Cartilage is much more elastic than bone; it is often referred to as "gristle." Some bone may begin as cartilage, which is later replaced by bone tissue.

Mature bone of mammals is *lamellated*, i.e., it is made up of thin plates (*lamellae*) of bone tissue. The plates occur in bundles. This arrangement offers increased resistance to shearing forces. The shape and arrangement of the lamellae differ in the two major types of mature bone (1) *spongy*, and (2) *compact*. In spongy bone, the matrix consists of a lamellated network of interlacing walls resembling the structure of a sponge. This form can be found in the skull and ribs. In compact bone, the bundles of lamellae are arranged in vertical cylinders around a central canal. This bone is found in the long bones of the arms and legs. The blood vessels and nerves run through the central canals of compact bone and send minute extensions into the bone substance. Great numbers of these vertical cylinders are needed to make up the thickness of a typical bone.

Bone grows by the addition of new bone to old bone. In spongy bone, new bone is deposited upon the old within the meshes of the lamellated network. In compact bone, new bone is primarily laid down on the outer surface. In both types, the bone is first laid down as immature (soft) bone, which gradually becomes mature bone, hard and rigid with calcification. Long, hollow bones, such as those in the arm or leg are made from compact bone. They grow in circumference by the deposition of bone on the outer surface of the shaft. At the same time, the inner cavity becomes enlarged by the resorption or eating away of bone tissue. The ends of long bones are not hollow, but consist of a sponge-like section of bone covered by a layer of compact bone and capped by cartilage on the joint surface where one bone moves against another. See Fig. 1.

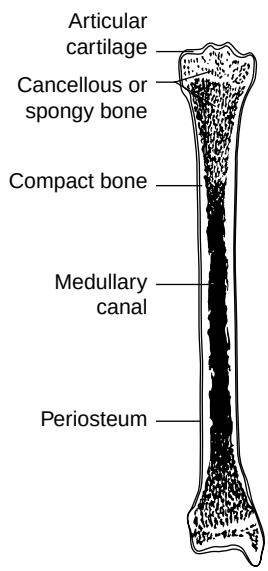

Fig. 1. Longitudinal section through the tibia. The red marrow is in the cancellous bone, and the yellow marrow is in the medullary canal. The periosteum is a layer that provides a smooth protective covering around the outer surface.

The structure of the cartilage, which caps the ends of bones that rub against one another in joints is adapted to bear the strain of pressure and to facilitate the smooth gliding of the opposing surfaces during motion.

Long bones provide an example of the principle that a hollow tube is stronger than a solid one. A long bone, such as the thighbone (*femur*) is subjected to enormous stresses in the form of bending forces and in weight-bearing. It gains maximal strength with a minimal amount of material by increasing the size of the hollow center, while adding to the tissue on the outer surface at the same time.

Lengthening of long bones is accomplished by the development of bone at the ends. Between the sponge-like bone ends and the shaft of the bone is an area of growth called the epiphysis or epiphyseal cartilage. Growth in length takes place only in this zone. The older cartilage becomes bone in the area next to the shaft, while new epiphyseal cartilage continues to form in the area next to the cap. When the epiphyseal area is completely replaced by bone tissue, the bone ceases to grow in length. Normally, in the human being, such growth is completed at about age 25, but physiologic disturbances may accelerate, retard, stop, or prolong growth. Hormones are important in the "sealing" of the epiphyses.

In infants and children, bones are softer than in adults, and yield readily to pressure or injury. This accounts for malformations, distortions in posture, foot defects, and other bone disorders. Young bones bend before breaking, and so-called "greenstick fractures" are common in children. In such a fracture, the shaft bends; and when the force is great enough, the bone on the convex surface breaks, much as a green twig may splinter along one side remaining intact on the other.

A deficiency of bone-making materials or disturbed processes of utilization of these materials may increase the softness and porous condition of bone. In the vitamin deficiency disease, rickets (lack of vitamin D), the shafts of long bones bend under strain, such as weight bearing. Consequently, the patient may have curved long bones throughout his life. When vitamin C is inadequate, changes may occur at the ends of the long bones in the line between the shaft and the epiphysis and under the periosteum as a result of hemorrhages in growing children. In the adult, only the periosteal changes occur. Older persons have bones that are more porous because their bodies are not able to utilize bone-making material adequately, while absorption of bone matrix continues.

Bone is covered by a membrane called the *periosteum*, which contains the vessels for supplying some of the nourishment to the bones. The periosteum is composed of two layers of connective tissue. The outer layer is a compact arrangement of specialized fibers liberally supplied with blood vessels and nerves. Because of its nerve supply, the periosteum is sensitive and accounts for any pain or pressure felt in the bone. The structure of the inner layer of the periosteum (*cambium*) is less compact and has fewer blood vessels of its own. The periosteum adheres to the bone by means of fibers of connective tissue, which anchor themselves in the bone tissue. The periosteum varies in thickness, being thinnest where the tendons of muscles are attached to bone, and thickest along the hollow portion of long bones.

Before birth and during infancy, *red marrow* is present in the long bones and in the network of spongy bones. Red marrow is one site of manufacture of the red blood cells. Blood vessels are threaded through the marrow, bringing oxygen and nutrients and taking away the waste products. The newly-made red blood cells enter the circulation by way of these vessels. When a person is about six years of age, changes begin to take place in the red marrow. *Yellow marrow*, or fatty marrow is formed, replacing the blood-making marrow; and most of the marrow cells change into fat cells. With these changes, the color of the marrow changes to yellow.

Yellow marrow is present in mature hollow bones. The formation of yellow marrow to replace red marrow takes place in a regular order beginning in the bones of the lower leg, followed by the thighbone, bones of the forearm, and finally in the bone of the upper arm. This replacement process also occurs in the epiphyses. In the adult, formation of red blood cells takes place only in the spongy flat bones of the skull, the ribs, pelvis, the bone of the spine, and the breastbone. See also **Blood**.

Biochemistry of Bone Formation

Bone formation is one of the earliest biological phenomena to be studied from a biochemical standpoint, yet its essential nature remains a subject of active research and speculation. Although the chief characteristic of bony tissue is its high content of inorganic salts, before considering the events associated with the formation of bone crystals some reference is necessary to the biogenesis of the organic portion within which the salts are deposited.

The bones originate from embryonic mesenchymal connective tissue cells that differentiate into bone-forming cells or osteoblasts. The formation of most embryonic bones occurs by calcification of a previously generated cartilaginous model, the remainder (intramembranous ossification) being the result of direct mineralization of connective tissue. In the former, the cartilage cells become hypertrophic and form centers of ossification from which cartilage is replaced centrifugally by bone cells. In the latter, calcification of the intercellular matrix occurs under the influence of osteoblasts that arise by transformation of connective tissue cells. The diaphysis, or shaft, elongates by calcification of the epiphyseal cartilage plate, which is continuously regenerated by osteogenic mesenchymal cells. It increases in diameter by accretion beneath the layer of connective tissue

covering the bone (the periosteum) and by concomitant removal from the endosteal surface of the marrow cavity.

Calcification results in the formation of the trabeculae of spongy bone, a form characterized by a high proportion of marrow and a profuse blood supply. Progressive deposition of new layers of bone, covered with osteoblasts, results in the generation of compact bone which is made up of units called haversion systems or osteones, each consisting of interwoven layers of bone oriented around a central vascular canal. The intercellular material is permeated by small spaces (lacunae) containing branched cells termed osteocytes. These cells are similar to osteoblasts, are rich in glycogen, and are necessary for the maintenance of bone cells. The osteones are subject to a continuing remodeling, apparently under the action of large, multinucleated osteoclasts located in tunnels that infiltrate the tissue prior to resorption.

The organic matrix of bone consists essentially of bundles of collagenous fibers imbedded in a ground substance. Although the general properties of bone collagen, which makes up over 90% of the dry fat-free organic matter, are similar to those of collagen derived from other forms of connective tissue throughout the body, the material present in osseous tissue apparently possesses some unique characteristic necessary for the nucleation of salt crystals. The ground substance is characterized chemically by the presence of mucopolysaccharides, including chondroitin sulfate, hyaluronic acid and keratosulfate, the physiological significance of which is still obscure.

The process by which bone crystals are deposited in the organic matrix, their internal structure, and their chemical constitution have been under investigation for many years. The mineral consists mainly of Ca^{2+} and PO_4^{3-} ions, with smaller amounts of CO_3^{2-}, OH^-, Mg^{2+}, Na^+, F^- and citrate^{3-}. However, the concentrations of the minor ions is uncertain owing to the occurrence of surface absorption phenomena, exchange with components of the fluid medium, and the possibility that some constituents (e.g., citrate) are in a separate phase. Electron microscopy suggests that the crystals are rod-like with a diameter of about 50 Å and that they may be oriented in chains along the collagen fibrils. X-ray diffraction and chemical analysis indicate that bone mineral has the crystal lattice structure and composition of a substituted hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. The architecture of the crystals provides for an enormous surface area in proportion to mass, thereby exposing the salts to intimate contact with constituents of the surrounding fluid. Exchange occurs actively, particularly in trabecular bone, not only between ions of the same species but also between dissimilar species: CO_3^{2-} for PO_4^{3-}, Sr^{2+} for Ca^{2+} and F^- for OH^-. The Ca:P molar ratio for bone is very close to the theoretical value for hydroxyapatite (1.67).

Studies on the formation of the bone salts have centered on the physiochemical concept that crystallization occurs when the concentration of Ca and P ions in the blood and circulating fluids exceeds the solubility product constant. Plasma P is present mainly as HPO_4^{2-}, in a smaller amount as $H_2PO_4^-$ and in minute concentrations as PO_4^{3-}. Observations on the calcification of cartilage *in vitro* indicate that the product $[Ca^{2-}] \times [HPO_4^{2-}]$ is the critical ion relationship in crystal formation, and it has been proposed that whereas the serum and extracellular fluid are normally undersaturated with respect to $CaHPO_4$, they are supersaturated with respect to bone salts. This proposal suggests that an ion gradient exists between the interstitial bone fluid and the extracellular fluid maintained by cellular activity, and it stresses the importance of the minor ions, particularly citrate^{3-}, in determining the degree of saturation. The production of citrate^{3-} by bone cells may determine whether the medium is undersaturated or supersaturated with respect to Ca^{2+} and HPO_4^{2-}, i.e., whether dissolution or deposition of bone salts occurs. It is further suggested that vitamin D and parathyroid hormone may exert their influence on bone metabolism by regulating the metabolic activity of the cells and hence the production of citrate.

The mechanism by which crystal formation is initiated is still obscure. Following the discovery of phosphatase in calcifying cartilage, the view became prevalent that the local action of this enzyme on some organic phosphate ester produced a high concentration of phosphate ion which exceeded the solubility product constant of bone mineral. This theory has been largely discarded in favor of a "seeding" mechanism which assumes that some component of the organic material (presumably the collagen or the mucopolysaccharide) furnishes the seeding sites. Reconstituted collagen fibers have the ability to induce crystal formation *in vitro* from stable solutions of Ca^{2+} and HOP_4^{2-} ions; however, it is difficult to prepare collagen that is completely free of mucopolysaccharides. Once the nuclei have been formed, crystallization proceeds spontaneously. Apart from the unexplained role of phosphatase, glycolysis appears to be a necessary accompaniment of bone salt formation; inhibitors of glycolysis interrupt crystallization in a reversible manner.

The biochemical remodeling process is central to several major diseases and disorders of bone. In osteoporosis, the mass of bone is reduced per unit volume which, in connection with other less complex structural materials, would be described as a lowering of density. In osteomalacia, there is deficiency (or failure) to mineralize the newly forming organic matrix of bone. Rickets in children is a manifestation of disorder in the remodeling process that has some parallels to osteomalacia.

The fundamentals, as just described, are now being subject to studies at the molecular level and targeting on chondro-osteogenetic DNA.

M.R. Urist and colleagues (University of California, Los Angeles) have been investigating bone cell differentiation and growth factors for a number of years. As pointed out by these researchers, the process of induced cell differentiation has been observed from measurements of the quantities of bone formed in response to implants of either bone matrix or purified bone morphogenetic protein (BMP) in extraskeletal and intraskeletal sites. The osteoprogenitor cell proliferation process has been well known for more than a century and is measured in reactions of periosteum and endosteum to injury, diet, vitamins, and hormones. Bone-derived growth factors (BDGF) stimulate osteoprogenitor cells to proliferate in serum-free tissue culture media. The mechanisms of action of BMP and BDGF are primarily local, but secondary systemic immunological reactions could have either permissive or depressive effects.

The researchers report on a survey of progress made in the field. The findings suggest that BMP and BDGF are mutually supportive, that is, the BMP initiates the covert stage and BDGF stimulates the overt stage of bone development. The effects of BMP are observed on morphologically unspecialized mesenchymal-type cells; the action of BDGF is shown only in tissue culture, ostensibly on morphologically differentiated bone cells. In their conclusions, the investigators (1983 reference) observe that bone is the only tissue in the body of higher vertebrates to differentiate continuously, remodel internally, and regenerate completely after injury. BMP induced development is irreversible. BDGF stimulation is reversible and comparable overall to the effects of somatomedin.

As reported by Hohmann and colleagues (University of Minnesota Medical School), regulation of bone mineralization and resorption has generally been attributed to blood-borne hormones, such as parathyroid hormone, calcitonin, and vitamin D. In vitro studies have demonstrated that vasoactive intestinal peptide (VIP) dramatically stimulates bone resorption. This action is probably mediated by way of high-affinity receptors for VIP similar to those recently identified in human osteosarcoma cells.

However, plasma levels of VIP are so low that a hormonal role for VIP in bone resorption seems unlikely. Thus, studies were conducted by Hohmann et al. to assess a cellular source that might deliver sufficient quantities of VIP to osseous cells and therefore regulate bone mineralization. In their conclusions, the group observed that because of its anatomical location and in vitro effect, it can be hypothesized that VIP may modulate bone resorption in vivo. Neural control of bone resorption may be important in other conditions in which calcium mobilization occurs, such as osteoporosis, lactation, and loss of mineral associated with zero gravity. Further neurophysiological studies may clarify the role of VIP and other transmitters in such states.

Bone Reconstruction. For many years, persons who suffered from the *shortening* of bones brought about by accidents, certain diseases, or genetic aberrations had little satisfactory recourse for improving the underlying condition. Rather crude methods were used wherein a piece of bone from some other part of the body or a donor was bolted onto the shortened bone, but seldom did the added bone meld well with the existing bone. Further, such operations were traumatic, partly as the result of surrounding soft tissue not lengthening sufficiently to accommodate the stretching required.

Although developed in the 1940s by a physician in the former Soviet Union, an improved technique was not adopted by free-world physicians until the early 1980s. Basically, the technique takes advantage of the fact that bone and accompanying soft tissue will grow if placed under *tension*. The method was developed by Gavriel A. Ilizarov and is referred to as the Ilizarov procedure. Operations of this type first were performed in the United States at the University of Maryland School of Medicine, Baltimore.

In the procedure, orthopedic surgeons first insert flexible pins through opposite ends of a bone. These pins, which radiate outward from a limb,

are attached to a ring structure that surrounds the limb so that the limb and accompanying tissue may be subjected to tension. By carefully serrating the bone, but not so deeply as to injure the marrow, the bone can be stretched progressively. Reports indicate that the bone grows about 1 cm over a period of 10 days. It requires about twice as long for the new bone to harden and, thus, the procedure requires a considerable span of time. A modification of the same procedure is used to straighten bones. According to physicians who have used the technique, the procedure does not involve the risks associated with bone grafting and other types of orthopedic surgery.

About a half-million operations had been performed in Russia prior to the knowledge reaching Western countries. This is explained by the fact that the procedure was developed in a remotely situated small town in western Siberia.

Cartilage

Caplan, in an excellent paper on cartilage (1984) succinctly describes the role of cartilage — a tissue whose properties are established not only by the properties of its cells, but by what the cells secrete. Cartilage is an elaborate network of giant molecules that cells deposit around themselves to form an extracellular matrix. These are among the largest molecules yet encountered in nature. The cartilage matrix includes large volumes of water and it is the structuring of water that yields the tissue's properties.

Over a century and a half ago, in 1837, Müller first produced the cartilage substance, chondrin, by steaming cartilage at high pressure. Chondroitin sulfate was not isolated until a half-century later, by Krukenberg. Davidson and Meyer (Columbia University) showed in 1955 that chondroitin sulfate is a repeating disaccharide, a type of polysaccharide or polymer consisting of sugars. More specifically, chondroitin sulfate consists of glucuronic acid and sulfated N-acetylgalactosamine in alternation. Research on the properties and further delineation of cartilage continued, with a breakthrough occurring in 1969 when Hascall and Sajdera (Rockefeller University) extracted intact the macromolecules that contain the chondroitin sulfate. This was an outgrowth of the investigators' study of nucleic acids, including DNA.

In the Caplan paper, the central, organization molecule of the proteoglycan in cartilage is described in detail and it is shown how the repeating disaccharide hyaluronic acid and proteoglycan make cartilage resilient, one of its most important properties. In one of his conclusions, Caplan observes that the process by which cartilage gives way to bone, allowing calcification and vascularization in the developing body, suggests a mechanism by which the body develops. It suggests that cartilage and bone include substances that profoundly affect other tissues. The idea could ultimately have major implications for the management of disease and it could also shed light on the developmental cycle of body tissues. Also observed — the elucidation of the structure and function of cartilage on the molecular level may yield the means by which the downward arc of the body's developmental program can someday be changed for the better. See also **Cartilage**.

Bone Disorders and Diseases

Fractures. A fracture is a broken bone. In a *closed fracture*, the bone is either cracked or completely broken in two, but there is no connecting wound from the break extending through the skin. In an *open fracture*, the bone is broken and bone fragments penetrate the surface of the skin; or an external object, such as a bullet, penetrates the skin and forms a connecting wound with the broken bone. Proper handling of a fracture is essential. Rough handling may cause a simple fracture to become an open fracture; and it may cause the bone fragments to injure the blood vessels, nerves, and other tissues.

Injury to the head may result in: (1) a *fracture*, in which the skull is broken or cracked; (2) a *depressed fracture*, in which the skull is broken, and fragments of bone are embedded in the brain tissue; or (3) a *concussion*, in which the brain is bruised by swelling resulting from hemorrhage.

A fracture or injury to the neck or spinal column usually causes intense pain. The pain in most cases radiates outward to other parts of the body, dependent upon which of the vertebrae is affected. Fractures high on the spinal column may result in pain in the arms or chest, while fractures lower down cause pain in the abdomen or legs. When an injury has affected the spinal cord, the patient may suffer a loss of sensation and ability to move the part of the body supplied by nerves from the spinal column at the point of fracture and below it.

An injury is termed a *dislocation* when a bone gets out of place at a joint. The joints are flexible sacs held in place by ligaments. Ligaments are tough fibrous bands of tissue that extend from one bone to the other, entirely surrounding the joint. In a dislocation, the ligaments and sacs are partially or completely torn, the bony surfaces may be fractured, and the blood vessels and nerves may be injured or torn. Dislocations of the shoulder and fingers are most common, followed by dislocations of the jaw, elbow, kneecap, and hip.

Surface-Active Biomaterials. As reported by Hench and Wilson (University of Florida), there is now a wide range of surface-active implants made from glasses, glass-ceramics, ceramics, and composites. All of them develop a bond with tissues that prevents motion at the interface. The implants are used in dental, maxillofacial, otolaryngological, and orthopedic surgery, although their use as load-bearing devices will require improvements in strength and fatigue resistance. The rate of bonding and the strength and stability of the bond vary with the composition and microstructure of the bioactive material. The mechanism of bonding generally involves a bioactive acellular layer rich in calcium phosphate, mucopolysaccharides, and glycoproteins, which provides an acceptable environment for collagen and bone mineral deposition. The biologically active surfaces of these materials uniquely influence the behavior of different cell types, and an understanding of the mechanisms involved has broad implications for the life sciences as well as for the surgical repair of the musculoskeletal system. See also **Collagen**; and **Rheumatoid Arthritis**.

Ionic Current and Bone Physiology. In an interesting research paper, Borgens (Purdue University) observes not only that bone is a structurally dynamic tissue that modulates its shape in response to changes in load and can heal itself spontaneously, but also that bone is electrically dynamic. Steady voltages have been reported along intact and damaged bone and short-lived voltages have been measured in response to loading. It has been suggested that such electrical phenomena underlie the physiology of adaptive remodeling and repair of the bone, but experimental evidence has been scant. After a series of experiments, the researcher reports that living bone drives an electric current through itself and into sites of damage. Such "fracture currents" consist of two components: an intense, decaying current dependent on bone deformation, and a stable, persistent current driven by a cellular battery. The latter is carried by chloride ions and, to a lesser extent, by sodium, magnesium, and calcium ions. Endogenous fracture currents are of the same polarity and similar magnitude as clinically applied currents that are successful in treating chronic non-unions in fractured bones. This suggests that the defect in biological non-unions may reside in the electrophysiology of repair. Borgens concludes his paper by observing — the idea that surface-detected injury potentials may help to control the response to damage is not restricted to bone, and this has been a fertile area of research since the mid-19th Century. Our modern understanding of current flow in developing cells and tissue has largely rendered the surface detection of bioelectric potentials as an obsolete descriptive technique. However, one idea engendered by these antiquated measurements is that electrical phenomena may help to control the tissues response to injury.

Acoustic Emissions from Bones. Characteristic sounds given off by materials, such as ceramics and metals, when they are stressed have been useful in assessing the integrity of welds and detecting cracks. Acoustic emissions (below the ultrasonic range of 20,000 Hz) may be useful in diagnosing bone fractures and for monitoring the mending of such fractures.

In the early 1970s, Hanagud and colleagues (Georgia Institute of Technology), and a bit later Yoon (Rensselaer Polytechnic Institute), conducted studies of acoustic emissions by bones. The studies involved the detection of emitted "noises" by bones under stress. In some experiments, machined animal bones (oven-dried or chemically conditioned to simulate the effects of the bone disease, osteoporosis) were tested. It was learned that the emitted noises were considerably more complex than stress-induced noises from plastics or metals. The researchers later tested noises from the bones of living humans. Although further research is needed, as pointed out by Maugh (see reference), acoustic emissions from bone under stress can supplement x-rays by identifying microfractures and pinpointing the time of healing. It is further pointed out that acoustic emission tests may eventually provide an indication for athletes who need to get back in training as soon as possible after injury.

Pressure Measured in Living Hip Joint. In 1984, an artificial femoral head was inserted into a patient's thigh bone in only one of some

50,000 like procedures completed that year. The event was newsworthy, however, because the artificial joint incorporated ten pressure sensors, an induction coil, and a small transmitter (engineered by Mann and colleagues, Massachusetts Institute of Technology). This instrumentation enabled scientists to monitor the pressure 253 times per second at ten discrete locations within the joint socket — as the patient walked, jogged, jumped, climbed stairs, and rose from a sitting position. In vivo measurements of this type had not been made before.

The principal observations: (1) Pressure is not uniformly distributed within the joint, but varies markedly from point to point; (2) pressures are much higher than had been expected; and (3) extraordinarily high pressures are exerted when rising from a sitting position.

As pointed out by Mann, traditional analysis of cartilage as an articulating surface is continuing, but such experimental systems are extremely limited, not least because they typically do not replicate the ebb and flow of water from the cartilage when it is under pressure. This water flow is key to the high performance of cartilage as a low-friction bearing. Further instrumental implants should be of much value to the field of orthopedics.

Osteomyelitis

An infection of the bone caused by pyogenic bacteria, mycobacteria, fungi (uncommon) and viruses (rare). The disease may range from acute infection to an indolent subacute condition to a recurring chronic infection. In about one-fifth of cases, infection is by the bacteremic (blood) route and is called *hematogenous osteomyelitis*, frequently affecting children, but also quite common among older people over 50 years of age. The disease occurs to some degree among all age groups. The bones most frequently infected are the femur, tibia, and humerus, which are all long bones. Recent statistics indicate that *Staphylococcus* aureus is the causative agent in nearly half of the cases. Also important are *Mycobacterium tuberculosis* (15% of cases); enteric gram-negative bacilli (13%); *S. pneumoniae* (5%); Group A *Streptococcus* (3%). *Staphylococcus epidermis*, *Bacteroides* species, *Nocardia asteroides*, and *Coccidioides immitis* are less frequently implicated. Authorities observe that although tuberculosis infections generally have been declining for several years, this infection still is commonly seen in osteomyelitis. Bone infections have been increasing among heroin addicts. The marked increase in reconstructive orthopedic surgery has contributed to osteomyelitis secondary to a contiguous focus of infection.

Early symptoms of osteomyelitis parallel those of numerous infections — chills, fever, and leukocytosis (high white cell count) accompanied by tenderness, swelling, and pain in the region of infected bones. Bacteremia (bacteria in blood) is present in over half of the cases. In about one-fifth of cases, hematogenous osteomyelitis becomes chronic and may extend over months or years. *Brodie's abscess* is a subacute form of hematogenous osteomyelitis. *Vertebral body osteomyelitis* usually results from bacteremias. *S. aureus* arising from skin infections, narcotic addiction, and urinary tract infections and endocarditis is implicated in over 50% of cases. The predominant symptom of vertebral body osteomyelitis is low back pain. There also may be paraspinal muscle spasms. Subgroupings of the disease include *pyogenic osteomyelitis* (lumbar vertebrae are affected) and *spinal tuberculosis* or *Pott's disease* (thoracic vertebrae are affected). In persons with sickle cell anemia, *Salmonella* is second to *S. pneumoniae* as a cause. Syphilitic osteomyelitis is uncommon.

Treatment of acute hematogenous osteomyelitis is parenteral administration of appropriate antibiotics over a period of several weeks. This therapy is usually successful. Important to the therapy is accurate determination of the microorganism responsible for the infection.

Secondary osteomyelitis developing from a contiguous focus of infection is the other major group of osteomyelitis diseases. This type of infection may follow a puncture wound or cat bite, or may be associated with infections resulting from thermal burns and complications arising from open reduction of fractures and reconstructive orthopedic surgery. Postoperative deep wound infections following total hip replacement are not uncommon. These infections may arise from pyogenic bacteria (*S. aureus* or enteric bacilli) or from normally noninvasive bacteria, such as *S. epidermis* or diphtheroids. These infections usually appear relatively soon after surgery. At a later time, deep infections may not be apparent for several months or even years. In one statistical study, it was found that such infections arise in 2.7% of such surgical procedures. Treatment is essentially by administration of antibiotics.

Osteoporosis

A disorder, the result of which is a decrease of bone mass in the absence of a mineralization defect. The bone remodeling process previously described in this entry, rather than maintaining an equilibrium condition in this disease, is biased toward a greater rate of bone resorption than of bone formation. This suggests that the disease derives from an alteration in the relationship (both quantitatively and qualitatively) of osteoclasts with osteoblasts. In osteoporosis, radiological examination will reveal decreases in bone density, thinning of the cortexes (outer layer of bone), and a loss of trabeculae (supporting fibers). Radiological examinations, however, may not be precisely indicative of the disease, particularly because of the possible presence of osteomalacic states, multiple myeloma, metastatic neoplasms, and hyperparathyroidism. Most commonly, osteoporosis is seen in older people, particularly in women, and is the fundamental underlying cause of skeletal fractures in middle-aged and elderly women.

Involutional osteoporosis appears to be a natural accompaniment of aging, particularly of women after menopause. This is classified as a metabolic bone disease. The condition is much less commonly seen in men and consequently appears to result from the poorly understood biochemical differentiation of males and females. The condition among females bears no known racial variation. Sedentary individuals are more prone to involutional osteoporosis because exercise tends to increase bone mass in either sex. Certain factors, including dietary intake of calcium and phosphate, protein and vitamin D metabolic abnormalities, and hormones, among others, have been suggested as contributing causes, but there is no hard evidence in these areas.

Normally, throughout most of life, the remodeling processes (bone formation and resorption) occur together, but not always simultaneously. A number of authorities have suggested that resorption may be made up of short, intense periods, whereas bone formation is a slower process that continues over longer periods. In older people with osteoporosis, resorption exceeds formation, and in view of the fact that resorption may occur as the faster of the two processes, this may account for the relatively rapid onset of osteoporosis at later stages in life.

Osteoporosis occurs in a number of patients who have been on *glucocorticoid therapy* for long periods of time. Endogenous glucocorticoid excess occurs in Cushing's syndrome, causing osteoporosis among other conditions. It appears that in persons taking glucocorticoids (for example, prednisone), the severity of osteoporosis varies more closely with the duration of therapy than with the dosage. Studies indicate that glucocorticoids increase bone resorptive surfaces, while they decrease bone formation. These factors, working together, can create a rapid rate of bone loss. Halting the therapy arrests the degradation, but there is no evidence that bone restoration will occur. Sometimes vitamin D will be used to improve the intestinal absorption of calcium.

Bone Densitometry. As reported by C.C. Johnston (Indiana University School of Medicine) and associates, "The relation of bone mass to fracture has been debated in the past. Because the values for bone mass in patients with fractures overlap substantially with the values in those with no fractures, it has been argued that measuring bone mass is not helpful." Bone mass, however, can be useful for predicting the risk of future fractures. It has been well established that nearly all fractures among the elderly are related, at least in part, to low bone mass. This has resulted from a number of large sample studies among all segments of the elderly population.

Currently, there are available a number of safe, accurate, and reliable means for measuring bone mass. These include single-photon absorptiometry, dual-energy photon absorptiometry, dual-energy x-ray absorptiometry, and quantitative computed tomography. The clinician who uses these tools can assist in making decisions pertaining to preventive measures and also monitor the success of therapy once commenced. See Johnston reference.

Etidronate as an Option for Treating Osteoporosis. Etidronate is a *bisphosphonate*, a class of compounds that are chemically related to pyrophosphate. These compounds, like pyrophosphate, are adsorbed to bone crystals. They differ, however, in that they resist enzymatic hydrolysis and thus have a long skeletal half-life. Etidronate therapy has been tested in a number of trials and has proved effective. In summarizing a report on tests made thus far, B.L. Riggs (Mayo Clinic and Foundation) observes, "In contrast to the pessimistic view held by many only a few years ago, it is now clear that postmenopausal osteoporosis can be treated effectively. The antiresorptive agents may be better suited to preventing osteoporosis than to treating it, since their ability to increase bone mass is limited. Sodium fluoride is the only agent stimulating bone formation

that consistently produces large gains in vertebral mass, but there is controversy about whether fluoride-treated bone has normal strength. In a recent randomized clinical trial, fluoride treatment did not reduce the rate of vertebral fractures. Thus, in the absence of a program for stimulating bone formation that has been demonstrated to increase bone strength, antiresorptive agents remain the mainstay of treatment. In this context, cyclical etidronate treatment is a welcome new option.

Hyperthyroidism sometimes increases bone resorption with accompanying loss of calcium and hydroxyproline through the urine.

Treatment and management of osteoporosis include mechanical devices, such as braces and corsets, analgesics to reduce pain, supervised exercises, regular periods of rest with proper postural position, and a number of drugs. Since the 1940s, estrogens have been used for treating women with the disease. Estrogens, which decrease bone resorption, have been shown to be effective in reducing fractures and the height loss frequently experienced with osteoporosis. Estrogens are used by physicians, with discretion, however, because of some disadvantages (renewal of vaginal bleeding, swelling of breasts, and the possible increase of risk of endometrial carcinoma). Where osteoporosis is age-related, calcium supplements and vitamin D therapy may be beneficial. Where recurrent fractures, height loss, and spinal deformity persist, the physician may consider the administration of sodium fluoride, phosphate, or parathyroid hormone.

Diet and Osteoporosis. The importance of dietary calcium in preventing osteoporosis is a controversial topic among medical professionals. In 1984, a widely accepted recommendation was made by a consensus panel (National Institutes of Health) on osteoporosis — all persons should consume at least 1000 milligrams of calcium per day. It was suggested that a lesser consumption of Ca could lead to osteoporosis. In the middle 1980s and continuing to the present, many millions of dollars are invested annually in the United States alone for calcium products. In the late 1980s, some researchers are observing that no body of evidence exists that would indicate a relationship between Ca intake and bone density within the population. Other researchers observe that, at best, the evidence in 1984 was tenuous and coupled with the reasoning that, even if ineffective, the Ca intake could cause no harm. One observer has gone so far as to designate Ca as "the laetrile of osteoporosis." Other researchers, of course, disagree, but there have been subsequent studies which indicate that the 1000 mg of Ca per day (except for postmenopausal women) may be high by perhaps 500 mg.

Riggs (Mayo Clinic) points out that his 1985–86 study applied only to adults. There is evidence showing that Ca intake in childhood and adolescence determines peak bone mass in adulthood. Those with greater peak bone mass are less likely to develop osteoporosis. Other researchers have indicated that their studies apply only to adults. Most researchers in the field do agree on one point — more evidence is needed before a final resolution of the question can be made.

Paget's Disease (Osteitis deformans)

This condition, characterized by abnormally thickened but weak bones, is believed to be caused by excessive activity of both the osteoblastic and osteoclastic cells. Some authorities postulate that an endocrine disturbance may be the root cause. The disease is found in about 4% of men over 40 years of age with an Anglo-Saxon heritage. Women are much less frequently affected. Familial connections have been observed, but no genetic details have been delineated. Normally the symptoms, including minor pain, are of such moderate proportions that the condition usually is not brought to the attention of a physician until a radiological examination is made for other purposes — or until considerable bone deformation has taken place. In its mild form, indomethacin therapy is used. Where the disease is more serious, calcitonins and diphosphanates may be used. Where the disease seriously affects the hip, replacement arthroplasty is generally suggested.

Osteomalacia

Sometimes defined as softening of the bones due to calcium deficiency, this disease may arise from a number of causes, essentially of a metabolic nature. The disease is frequently indistinguishable clinically and radiologically from osteoporosis. In cases where there are hereditary disorders of vitamin D metabolism (hypovitamins D) or renal tubular acidosis, clinical manifestations are more easily identifiable. Increased renal clearance of phosphate is the principal indicator of hereditary vitamin D-resistant *rickets*. The indicated treatment for this condition is high dosages of vitamin D with a phosphate supplement. Many years ago, prior to current appreciation of the functions and importance of the various vitamins, ricketts occurred widely in infants and children, creating deformities that had to be carried throughout life. The disease is characterized by defective ossification caused by faulty deposition of calcium salts at the growing ends of the bones, generally ascribed to a deficiency of vitamin D.

Osteopetrosis

Because of the similarity of spelling, this disorder should not be confused with osteoporosis. Osteopetrosis, sometimes called *Marble bone disease*, is a condition discovered in 1904 by Albers-Schönberg in Germany. It is a rare disease; only a few hundred cases have been reported over the last half-century. As pointed out by Sly and colleagues (see reference), osteopetrosis with renal tubular acidosis and cerebral calcification was first identified as a recessively inherited syndrome in 1972. Since then, two principal genetic types have been distinguished — a benign autosomal dominant form with relatively few symptoms, and a severe autosomal recessive type (malignant form) characterized by multiple complications and early death. It has been suggested that intermediate forms of osteopetrosis also may exist and that they may be more common than generally recognized. Patients with this disorder who have been studied present a virtual absence of the carbonic anhydrase II peak on high-performance liquid chromatography, of the esterase and carbon dioxide hydratase activities of carbonic anhydrase II, and of immunoprecipitable isozyme II. The researchers conclude that the disease is caused by a distinct inborn error characterized by a deficiency of carbonic anhydrase II. The researchers also point out that the distribution of the syndrome is striking, with more than half the known cases observed in families from Kuwait, Saudi Arabia, and North Africa, with an increased frequency of consanguineous marriages, particularly in the Bedouin tribes.

Traumatic Disorders of Bones
